ABSTRACT

Due to the mounting evidence that RNA structure plays a critical role in regulating almost any physiological as well as pathological process, being able to accurately define the folding of RNA molecules within living cells has become a crucial need. We introduce here 2-aminopyridine-3-carboxylic acid imidazolide (2A3), as a general probe for the interrogation of RNA structures in vivo. 2A3 shows moderate improvements with respect to the state-of-the-art selective 2'-hydroxyl acylation analyzed by primer extension (SHAPE) reagent NAI on naked RNA under in vitro conditions, but it significantly outperforms NAI when probing RNA structure in vivo, particularly in bacteria, underlining its increased ability to permeate biological membranes. When used as a restraint to drive RNA structure prediction, data derived by SHAPE-MaP with 2A3 yields more accurate predictions than NAI-derived data. Due to its extreme efficiency and accuracy, we can anticipate that 2A3 will rapidly take over conventional SHAPE reagents for probing RNA structures both in vitro and in vivo.

INTRODUCTION

RNA structure is a jack-of-all-trades. Besides being crucial to the function of structural non-coding RNAs (ncRNAs), RNA structural elements are now widely recognized as key players in almost any essential biological process, ranging from transcriptional and post-transcriptional control of gene expression, to catalysis and sensing of environmental stimuli such as metabolite and temperature changes (1).

In light of its importance, being able to define the structure of an RNA molecule is a key need towards understanding its mechanism of action. It is however still impossible for most RNAs to define their secondary structures starting solely from their primary sequence. Main reason for this is the huge size of the RNA folding space, so that a n nucleotides-long RNA can theoretically fold in up to $1.8^n$ distinct conformations (2).

A widely used approach to define the putative structure of an RNA based on its sequence relies on predicting its minimum free energy (MFE) structure, the theoretically most stable structure, based on a set of experimentally-determined thermodynamic parameters known as nearest neighbor model (or Turner rules) (3). Unfortunately, the accuracy of MFE predictions is very limited, with only ~66% of predicted base pairs actually occurring in experimentally-validated structures (4). This is likely to be a consequence of the fact that, beyond thermodynamics, a multitude of cellular factors play a key role in regulating RNA folding in the context of the living cell, such as RNA post-transcriptional modifications, protein binding, crowding and many others (5–7). The accuracy of thermodynamics-driven RNA structure determination algorithms can be however improved by incorporating experimental constraints from RNA footprinting experiments. These experiments are based on the use of specific chemicals or nucleases to probe the conformation of RNA residues. When informed with these experimentally-derived constraints, the accuracy of RNA structure prediction algorithms greatly improves (8–12).

Only few chemical probes can readily permeate cell membranes and can thus be used in vivo, while the majority of them are only suitable for in vitro and ex vivo RNA structure probing experiments. Two classes of compounds are mainly used to date. On the one hand, nucleobase-specific probes, such as dimethyl sulfate (DMS) and 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC), can be respectively used to probe adenine (A) and cytosine (C), or guanine (G) and uracil (U) bases (13,14). On the other hand, selective 2'-hydroxyl acylation analyzed by primer extension (SHAPE) reagents can be used to probe the local flexibility of the RNA backbone in a nucleobase-independent fashion (15), as they can form adducts with the 2'-OH of the ribose moiety. Among SHAPE reagents, 3 have been extensively characterized: 1-methyl-7-nitroisatoic anhydride (1M7), 2-methyl-3-furoic acid imidazolide (FAI) and 2-
methylnicotinic acid imidazolide (NAI) (16,17), with the latter being the most effective at probing RNA in living cells (18,19).

Typical readout of RNA probing experiments is the detection of reverse transcription (RT) drop-off events induced by the probing reagent-modified RNA bases (20). More recently, it has been shown that, by either using specific RT enzymes or RT conditions, it is possible to favor the RT read-through on modified RNA bases, ultimately resulting into the recording of multiple modification sites as mutations within the same cDNA molecule. These techniques have been therefore dubbed mutational profiling approaches (MaP) (21–24) and are rapidly taking over traditional RT drop-off methods.

While the use of SHAPE compounds over nucleobase-specific probes has in theory a considerable advantage, as they enable the unbiased probing of all four RNA bases, reagents such as DMS still exhibit a higher signal-to-noise ratio in MaP experiments. To this end, we here sought to optimize in vivo RNA probing by synthesizing six new SHAPE reagents and by assaying their ability to probe in vivo Gram-positives, Gram-negatives and mammalian cells. One of these compounds, 2-aminopyridine-3-carboxylic acid imidazolide (2A3), showed both increased reactivity with RNA and higher permeability to biological membranes, resulting in a significantly higher signal-to-noise ratio when compared to NAI. Importantly, when used to perform experimentally-informed prediction of in vivo RNA structures, 2A3 produced markedly more accurate predictions than NAI.

**MATERIALS AND METHODS**

**Synthesis of SHAPE reagents**

For the design of novel SHAPE reagents, we first compiled a list of commercially-available carboxylic acids. We then selected those containing nitrogen groups or for which piled a list of commercially-available carboxylic acids. We sought to optimize in vivo RNA probing by synthesizing six new SHAPE reagents and by assaying their ability to probe in vivo Gram-positives, Gram-negatives and mammalian cells. One of these compounds, 2-aminopyridine-3-carboxylic acid (2A3), showed both increased reactivity with RNA and higher permeability to biological membranes, resulting in a significantly higher signal-to-noise ratio when compared to NAI. Importantly, when used to perform experimentally-informed prediction of in vivo RNA structures, 2A3 produced markedly more accurate predictions than NAI.

**Extraction of native deproteinized E. coli rRNAs**

Deproteinized *Escherichia coli* RNA was prepared essentially as previously described (23), with minor changes. Briefly, a single colony of *E. coli* K-12 DH10B was picked and inoculated in LB medium without antibiotics, then grown to exponential phase (OD<sub>600</sub> ~ 0.5). 2 ml aliquots were collected by centrifugation at 1000 × g (4°C) for 5 min. Cell pellets were resuspended in 1 ml of Resuspension Buffer [15 mM Tris–HCl pH 8.0; 450 mM sucrose; 8 mM EDTA], and lysozyme was added to a final concentration of 100 μg/ml. After incubation at 22°C for 5 min and on ice for 10 min, protoplasts were collected by centrifugation at 5000 × g (4°C) for 5 min. Pellets were resuspended in 120 μl Protoplast Lysis Buffer [50 mM HEPES pH 8.0; 200 mM NaCl; 5 mM MgCl₂; 1.5% SDS], supplemented with 0.2 μg/μl Proteinase K. Samples were incubated for 5 min at 22°C and for 5 min on ice. Sample was then extracted 2 times with phenol:chloroform:isoamyl alcohol (25:24:1), pre-equilibrated three times with RNA folding buffer [50 mM HEPES pH 8.0; 200 mM NaCl; 5 mM MgCl₂], and once with chloroform. 20 U SUPERase-In<sup>™</sup> RNase Inhibitor (ThermoFisher Scientific, cat. AM2696) were then added and RNA was equilibrated at 37°C for 20 min prior to probing.

**Ex vivo probing of E. coli rRNAs**

180 μl of deproteinized *E. coli* rRNAs in RNA folding buffer, pre-equilibrated at 37°C for 20 min, were mixed with...
20 µl of each SHAPE compound (assuming complete conversion, stocks should be ~1 M, resulting in a final concentration of 100 mM in the probing reaction). RNA was then allowed to react at 37°C for 15 min, with moderate shaking, after which 200 µl of 1 M DTT were added, to quench the reaction. Samples were then vortexed briefly and 1 ml of ice-cold QIAzol Lysis Reagent (Qiagen, cat. 79306) was added to each sample, followed by extensive vortexing.

**In vivo probing of E. coli cells**

A single colony of *E. coli* K-12 DH10B was picked and inoculated in LB medium without antibiotics, then grown to exponential phase (OD₆₀₀ ~ 0.5). 2 ml aliquots were collected by centrifugation at 1000 × g for 5 min. Cell pellets were resuspended in 450 µl 1 × PBS (pH 7.4) and 50 µl of each SHAPE compound were added, followed by brief vortexing. Cells were allowed to react at 37°C for 20 min, with moderate shaking, after which 500 µl of 1 M DTT were added, to quench the reaction. Cells were pelleted by centrifugation at 17 000 × g for 2 min (4°C) and supernatant discarded. Cell pellets were then resuspended in 100 µl of Buffer A [10 mM Tris pH 8.0; 100 mM NaCl], supplemented with 5 U SUPERase•In™ RNase Inhibitor, by vigorously vortexing for 30 s. 25 µl of Buffer B [50 mM EDTA; 120 mM Tris pH 8.0], supplemented with 100 µg/ml final lysozyme, were then added, followed by 30 s vortexing. Samples were incubated 1 min at room temperature, after which 125 µl of Buffer C [0.5% Tween-20; 0.4% sodium deoxycholate; 2 M NaCl; 10 mM EDTA] were added to lyse protoplasts. Samples were then incubated at room temperature for 5 min, after which 100 µl of lysate were transferred to 1 ml ice-cold QIAzol and thoroughly mixed by vortexing. In vivo probing of *B. subtilis* cells

A single colony of *Bacillus subtilis* 168 was picked and inoculated in LB medium without antibiotics, then grown to exponential phase (OD₆₀₀ ~ 0.5). 2 ml aliquots were collected by centrifugation at 1000 × g for 5 min. Cell pellets were resuspended in 450 µl 1 × PBS (pH 7.4) and 50 µl of each SHAPE compound were added, followed by brief vortexing. Cells were allowed to react at 37°C for 20 min, with moderate shaking, after which 500 µl of 1 M DTT were added, to quench the reaction. Cells were pelleted by centrifugation at 17 000 × g for 2 min (4°C) and supernatant discarded. Cell pellets were then resuspended in 100 µl of Buffer A [10 mM Tris pH 8.0; 100 mM NaCl], supplemented with 5 U SUPERase•In™ RNase Inhibitor, by vigorously vortexing for 30 s. 25 µl of Buffer B [50 mM EDTA; 120 mM Tris pH 8.0], supplemented with 100 µg/ml final lysozyme, were then added, followed by 30 s vortexing. Samples were incubated 1 min at room temperature, after which 125 µl of Buffer C [0.5% Tween-20; 0.4% sodium deoxycholate; 2 M NaCl; 10 mM EDTA] were added to lyse protoplasts. Samples were then incubated at room temperature for 5 min, after which 100 µl of lysate were transferred to 1 ml ice-cold QIAzol and thoroughly mixed by vortexing.

**In vivo probing of HEK293 cells**

HEK293 cells were grown in DMEM (4.5 g/l d-glucose), supplemented with 10% heat-inactivated FBS, 0.1 mM NEAA, 1 mM sodium pyruvate, 25 U/ml penicillin and 25 µg/ml streptomycin, at 37°C (5% CO₂), to ~75% confluency. Cells were then covered with a thin layer of trypsin–EDTA (0.25%) solution, incubated at room temperature for 1 min, then dissociated by pipetting up and down with complete medium. Cells were centrifuged at 180 × g for 1 min and medium discarded. Cells were then resuspended in 450 µl 1 × PBS (pH 7.4) and 50 µl of each SHAPE compound were added, followed by gentle mixing by tapping the tube. Cells were allowed to react at 37°C for 15 min, with moderate shaking, after which 500 µl of 1 M DTT were added, to quench the reaction. Cells were pelleted by centrifugation at 10 000 × g for 1 min (4°C) and supernatant discarded. Cells pellets were lysed by direct addition of 1 ml ice-cold QIAzol, followed by a brief incubation at 56°C for 5 min to completely dissolve cell aggregates.

**Total RNA extraction**

After samples have been collected in 1 ml QIAzol, 200 µl of chloroform was added, followed by vigorous vortexing for 15 s. Samples were then incubated at room temperature for 2 min, after which they were centrifuged at 12 500 × g for 15 min (4°C). After centrifugation, the upper aqueous phase was transferred to a clean 2 ml tube, and mixed with 2 volumes of 100% ethanol by vigorous vortexing. The entire volume was then transferred to an RNA Clean & Concentrator™-5 column (Zymo Research, cat. R1015) and RNA was purified as per manufacturer instructions. RNA integrity was ensured by gel electrophoresis on a denaturing 2% agarose gel. Besides samples treated with I6, all other samples appeared to be perfectly intact. Before proceeding to library preparation, traces of genomic DNA were removed by treatment with 2 U TURBO™ DNase (ThermoFisher Scientific, cat. AM2239) at 37°C for 20 min.

**SHAPE-MaP library preparation**

Total RNA was first fragmented to a median size of 150 nt by incubation at 94°C for 8 min in RNA Fragmentation Buffer [65 mM Tris–HCl pH 8.0; 95 mM KCl; 4 mM MgCl₂], then purified with NucleoMag NGS Cleanup and Size Select beads (Macherey Nagel, cat. 744970), supplemented with 10 U SUPERase•In™ RNase Inhibitor, and eluted in 2 µl (for HIV RT and TGIRT-III) dNTPs (10 mM each), then purified with Nuclease Inhibitor, 50 U TGIRT-III RT Buffer [250 mM Tris–HCl pH 8.3; 375 mM KCl; 40 mM MgCl₂], 0.5 µl DTT 0.1 M, 5 U SUPERase•In™ RNase Inhibitor and 5 U HIV RT (Worthington Biochemical Corporation, cat. HIVRT). For TGIRT-III, reaction was supplemented with 1 µl 5 × RT Buffer [250 mM Tris–HCl pH 8.3; 375 mM KCl; 15 mM MgCl₂], 0.25 µl DTT 0.1 M, 5 U SUPERase•In™ RNase Inhibitor and 50 U TGIRT-III RT (InGex, cat. TGIRT-50). For SSII, reaction was supplemented with 1 µl 5 × RT Buffer [250 mM Tris–HCl pH 8.3; 375 mM KCl], 0.5 µl DTT 0.1 M, 0.25 µl MnCl₂ 120
mM, 5 U SUPERase•In™ RNase Inhibitor and 50 U SuperScript II RT (ThermoFisher Scientific, cat. 18064014). Reactions were incubated at 25°C for 10 min to allow partial primer extension, followed by 2 h at 37°C (for HIV RT), 2 h at 57°C (for TGIRT-III) or 3 h at 42°C (for SSII). SSII and HIV RT were heat-inactivated by incubating at 75°C for 20 min. As TGIRT-III tightly binds the cDNA-RNA complex, 0.5 μg of Proteinase K were added and reaction was incubated at 37°C for 20 min, after which 0.5 μl of a 1:2 dilution of protease inhibitor cocktail (Sigma Aldrich, cat. P9599) in water was added to stop the reaction. For SSII, the buffer exchange step was omitted. Instead, 6 mM final EDTA was added to chelate Mn2+ ions, followed by 5 min incubation at room temperature and addition of 6 mM final MgCl2. Reverse transcription reactions were then used as input for the NEBNext® Ultra II Non-Directional RNA Second Strand Synthesis Module (New England Biolabs, cat. E6111L). Second strand synthesis was performed by incubating 1 h at 16°C, as per manufacturer instructions. 

DsDNA was purified using NucleoMag NGS Clean-up and Size Select beads, and used as input for the NEBNext® Ultra™ II DNA Library Prep Kit for Illumina® (New England Biolabs, cat. E7645L), following manufacturer instructions.

Analysis of SHAPE-MaP data

All the relevant data analysis steps have been conducted using RNA Framework v2.6.9 (27). Reads pre-processing and mapping was performed using the rf-map module (parameters: -ctn -cnn 0 -cgo -cq5 20 -b2 -mp -very-sensitive-local). Reads were trimmed of terminal Ns and low-quality bases (Phred < 20). Reads with internal Ns were discarded. Mapping was performed using the ‘very-sensitive-local’ preset of Bowtie2 (28). The mutational signal was derived using the rf-count module (parameters: -m -rd), enabling the right re-alignment of deletions. Grid search of optimal slope/intercept pairs was performed using the rf-jackknife module (parameters: -rp -md 600 -nlp -v) and ViennaRNA package v2.4.11 (29), disallowing isolated base-pairs, setting the maximum base-pairing distance to 600 nt and enabling the relaxed structure comparison mode (8) (a base-pair i/j is considered to be correctly predicted if any of the following pairs exist in the reference structure: i/j; i − 1/j; i + 1/j; i/j − 1; i/j + 1).

Reference structure of rRNAs

16S and 23S rRNA reference structures for E. coli and B. subtilis were obtained from the Comparative RNA Web (30). 18S and 28S rRNA reference structures for H. sapiens were obtained from RNAcentral (31).

Generation of Receiver Operating Characteristic (ROC) curves

For the generation of ROC curves, the mutation frequency threshold was linearly varied from 0 to 1 with a step of 0.001, calculating at each increment the number of unpaired (true positive) and base-paired (true negative) residues (according to the accepted reference rRNA structures), whose mutation frequency exceeded that of the threshold. Terminal base-pairs (beginning/end of helices and isolated base-pairs) were excluded. For in vivo samples, only solvent-accessible bases were considered, as previously described (32). For solvent accessible surface area (SASA) calculation, ribosome structures were obtained from the Protein Data Bank, using accessions 5IT8 (E. coli), 6HA1 (B. subtilis) and 4UG0 (H. sapiens) in CIF format and converted to PDB format using PyMOL (v2.3.5). SASA per residue was then calculated using POPS (v3.1.2) and a probe radius of 3 Å. Accessible residues were defined as those residues with a SASA > 2 Å. Area under the curve (AUC) was calculated using the MESS package (v0.5.6) for R.

Signal-to-noise estimation

From reference rRNA structures in dot-bracket notation, we extracted all hairpin-loops with a stem length ≥3 and a loop size ≥3, using the regular expression ‘(i[(i[3]\{_\}{3}])[i][j]]’. For each hairpin-loop, we then calculated the median reactivity on the first and last two bases of the loop and the median reactivity on the three bases of the stem preceding and following the loop. The signal-to-noise value was then calculated as the ratio between the median reactivity across all the loops and the median reactivity across all the stems.

RESULTS

Comparison of RT enzymes for SHAPE-MaP

In a first attempt to optimize the signal-to-background ratio of SHAPE mutational profiling approaches (SHAPE-MaP), we sought to find the best reverse transcription conditions. To this end, we extracted deproteinized total RNA from E. coli cells, under conditions previously shown to preserve the native RNA folding (8,23,33) and probed it in solution with NAI (or neat DMSO as a control). We then performed reverse transcription using three different reverse transcriptases: SuperScript II (SSII) in Mn2+-containing buffer, thermostable group II intron RT (TGIRT-III) and HIV RT (22,24,34). These enzymes have been previously shown to be able to generate mutational signatures in cDNA when reading through SHAPE adducts (SSII), DMS-induced alkylations (SSII and TGIRT-III), or N-cyclohexyl-N’-(2-morpholinoethyl)carbodiimide metho-p-toluenesulfonate (CMCT) adducts (HIV RT). Analysis of the distribution of per-base mutation frequencies across 16S and 23S rRNAs showed that, while TGIRT-III has lower background mutation frequencies compared to SSII (median DMSO control: 0.75 × 10⁻³ for TGIRT-III versus 2.19 × 10⁻³ for SSII) as previously reported (22), SSII shows a higher and more significant increase in the mutation rates measured in the NAI treated sample with respect to the DMSO control (ratio median NAI versus DMSO: 2.95 for SSII, 1.37 for TGIRT-III and 1.16 for HIV RT, Supplementary Figure S1A). Accordingly, receiver operating characteristic (ROC) curves built with respect to unpaired versus paired residues from phylogenetically-inferred E. coli rRNA secondary structure models (30) and inspection of SHAPE-MaP signals confirmed the higher ability of SSII to translate SHAPE adducts on structurally-flexible bases into a
mutational signature (Supplementary Figure S1B, C). Altogether, these results identify SSII in Mn²⁺-containing buffer as the optimal RT enzyme for SHAPE-MaP experiments.

**Synthesis of six novel candidate SHAPE reagents**

While designing new candidate SHAPE compounds, we sought to meet the following requirements: (i) permeable to biological membranes (suitable for *in vivo* probing experiments); (ii) high signal over background (deriving from a good tradeoff between slow hydrolysis in water, reactivity with RNA and membrane permeability); (iii) easy and safe to synthesize. The two best-characterized *in vivo* SHAPE reagents to date are NAI and FAI. These compounds can be easily synthesized via the carbonyl/imidazole (CDI)-mediated activation of carboxylic acids, resulting in the corresponding carboxylic acid imidazolide, an activated carbonyl, that can acylate nucleophiles present in the system, especially 2′ hydroxy groups of RNA. We decided to adopt the same strategy, trying to optimize the acylating group. To this end, we selected seven commercially-available carboxylic acids, preferring those containing nitrogen groups or for which the putative adduct-forming group had a pKₐ in water close to (or slightly above) 7 (Table 1; see Materials and Methods).

We then evaluated all reagents for their ability to react with structurally-flexible RNA residues using *E. coli ex vivo* depurinized total RNA and NAI probing as the gold standard. We further discarded isoquinoline-6-carboxylic acid imidazolide (I6) as it was too reactive, hence resulting in very fast RNA degradation (data not shown). When looking at overall distributions of mutation rates, indoline-5-carboxylic acid imidazolide (I5) and 1-methylimidazole-4-carboxylic acid imidazolide (1M4) showed a lower reactivity towards RNA compared to NAI (median: 3.07 × 10⁻³ for I5, 4.50 × 10⁻³ for 1M4). Oppositely, the other four compounds, nicotinic acid imidazolide (NIC), benzotriazole-5-carboxylic acid imidazolide (B5), 6-aminopyridine-3-carboxylic acid imidazolide (6A3) and 2-aminopyridine-3-carboxylic acid imidazolide (2A3), all showed increased reactivity compared to NAI (median: 8.90 × 10⁻³ for NIC, 9.90 × 10⁻³ for B5, 11.9 × 10⁻³ for 6A3 and 15.2 × 10⁻³ for 2A3), with 2A3 having ~2.4X higher mutation frequencies than NAI (Figure 1A). ROC curves built with respect to unpaired versus paired residues from *E. coli* rRNAs revealed nearly comparable accuracies for 6A3, B5, NIC and 2A3, with NIC and 2A3 showing a slightly higher area under the curve (AUC), independently of DMSO background signal subtraction (Figure 1B and Supplementary Figure S2A). This intrinsically implies that these two reagents have a slightly higher signal-to-noise ratio with respect to NAI, as demonstrated by the higher mutation frequencies observed on single-stranded RNA regions (Figure 1C). To systematically quantify the actual signal-to-noise ratio of the different reagents, we extracted all the individual hairpin-loops from the known structures of *E. coli* 16S and 23S rRNAs, and calculated the median mutation frequency across the first and last two bases of the loop, versus the three stem bases preceding or following the loop (Supplementary Figure S2B). Notably, the ratio between the median loop reactivity and the median stem reactivity for 2A3 (4.01), B5 (4.01) and NIC (4.19) was higher than that of NAI (3.59), confirming that these reagents might represent better choices for *in vivo* RNA probing.

**2A3 outperforms NAI at probing RNA *in vivo***

Spurred by these promising results, we decided to test the ability of these newly synthesized compounds to permeate biological membranes to probe RNA within living cells. To this end, we employed *E. coli*, *B. subtilis* and HEK293 cells as representatives of the three major cell types in research labs: Gram-negative, Gram-positive and mammalian cells.

At first, we looked again into the distribution of mutation frequencies for the different reagents. Unexpectedly, while the observed distributions for HEK293 cells approximately mirrored those observed on *E. coli ex vivo*-modified RNAs (Supplementary Figure S3A), we observed that, for both *E. coli* and *B. subtilis*, mutation frequency distributions for most reagents, including NAI, were extremely close to those of the control DMSO sample (Figure 2A and Supplementary Figure S3B). On the other hand, 2A3 showed significantly higher mutation frequencies compared to NAI (ratio median 2A3 versus NAI: 2.74 in *e. coli*, 1.61 in *B. subtilis* and 1.77 in HEK293), independently of the probed cell type, partially followed by B5 in *B. subtilis* and NIC in HEK293 cells.

Oppositely to what we observed for the *ex vivo*-probed RNAs, ROC curves built with respect to unpaired versus paired residues from *E. coli*, *B. subtilis* and *H. sapiens* rRNAs (calculated on residues that are solvent-exposed in the respective ribosome crystal structures; see Materials and Methods) revealed a marked difference in sensitivity/specifcity of NAI compared to 2A3, with 2A3 showing up to 17–20% increased discrimination of unpaired versus paired residues, independently of DMSO background signal subtraction (AUC *E. coli*: 0.825/0.874 for 2A3 −/+ DMSO subtraction, 0.625/0.708 for NAI −/+ DMSO subtraction; Figure 2B and Supplementary Figure S4–5). Accordingly, quantification of the SHAPE-MaP signal on loops versus stem regions confirmed the strikingly higher signal-to-noise ratio of 2A3 (*E. coli*: 3.47; *B. subtilis*: 2.36; HEK293: 3.0) with respect to NAI (*E. coli*: 1.33; *B. subtilis*: 1.56; HEK293: 2.08), independently of the examined cell type (Figure 2C. D and Supplementary Figure S6). Base reactivity distributions for 2A3-modified RNAs on unpaired, internally-paired and terminally-paired bases, under all the analyzed conditions, appeared to be in line with those previously reported for other SHAPE reagents (35) (Supplementary Figure S7).

Deeper inspection of SHAPE-MaP signals revealed that, regions of bacterial ribosomes that were almost completely blind to NAI and most of the other reagents, were instead partially accessible to B5 and readily probed with high efficiency by 2A3, with mutational signatures in strong agreement with the known rRNA structure (Figure 3A and Supplementary Figure S8). In these regions, not only 2A3 effectively probed most RNA loops, but also it better captured local nucleotide dynamics. As an example, base U₁₀₃₂ of *E. coli* 23S rRNA is hyperreactive to 2A3, but almost completely unreactive to any other tested reagent, including NAI (Figure 3A). Coherently, analysis of this base in the

Chemical structure, full name and acronym of the SHAPE reagents tested in this study. NAI, used as a standard, is reported for comparison.

context of the crystal structure of the fully assembled *E. coli* ribosome (36) reveals its extreme flexibility, as it is twisted, completely flipping out of the parent helix (Figure 3B). Oppositely, a large loop of 19 contiguous single-stranded residues between positions 1124 and 1181 showed very low reactivities. Notably, this loop has a very low B factor in the crystal, suggesting that these residues are weakly dynamic (lowly flexible) in the context of the ribosome. In agreement with this observation, these residues became highly reactive towards 2A3 upon deproteinization (Supplementary Figure S9). Similarly, the hyperreactivity of U1032 was abrogated upon rRNA deproteinization. In HEK293, although NAI readily accessed most regions of the ribosome, showing very similar reactivity patterns to the other tested reagents, we observed that probing with 2A3 (as well as with NIC) resulted in a stronger and neater SHAPE-MaP signal (Supplementary Figure S10).

2A3 markedly improves the accuracy of RNA structure prediction

To definitively prove the better suitability of 2A3 for *in vivo* RNA folding studies, we used SHAPE-inferred reactivities to perform experimentally-driven RNA structure
Figure 1. Comparison of SHAPE reagents under ex vivo conditions. (A) Boxplot of SHAPE–MaP mutation frequencies for *E. coli* 16S and 23S rRNAs probed ex vivo after deproteinization. Box plots span the interquartile range (from Q1 to Q3). The grey area spans from the median in the DMSO sample (control) to the median in the NAI sample (reference). (B) ROC curves for all tested SHAPE reagents, calculated with respect to the accepted phylogenetically-inferred 16S and 23S rRNA structures from the Comparative RNA Web (30). The inset reports the area under the curve (AUC) for each compound. (C) Sample of SHAPE–MaP mutation frequencies for all tested compounds across a region spanning nucleotides 567 to 884 of *E. coli* 16S rRNA. Colored bases are those whose mutation frequencies exceed by 2-fold the median mutation frequency in the analyzed region. The accepted structure is reported as an arc plot.

modeling. SHAPE reactivities can be incorporated into thermodynamics-based prediction algorithms by converting them into pseudo-free energy contributions (8). This conversion relies on the use of two empirically-determined parameters, the slope (*m*) and the intercept (*b*). As these parameters depend on the experimental setup and on the employed reagent, we first used the ViennaRNA Package 2.0 (29) to perform a grid search of the optimal *m/b* pairs for NAI and 2A3 for *E. coli* rRNAs, in order to avoid skewing prediction results because of the use of the same *m/b* pair for both reagents (Figure 4A). For each *m/b* pair, we calculated the geometric mean of the prediction’s sensitivity (the fraction of known base pairs correctly predicted) and positive predictive value (PPV; the fraction of predicted pairs that are present in the known reference structure) for both 16S and 23S rRNAs. Notably, grid search already revealed that the accuracy of 2A3-driven predictions was largely independent of the employed slope/intercept pair and that, even the most accurate NAI-driven prediction (*m*: 2.2; *b*: −0.8; geometric mean of PPV/sensitivity: 0.67) was ~10% less accurate than most 2A3-driven predictions, independently of the used *m/b* pair and ~18% less accurate that the top-scoring 2A3-driven prediction (*m*: 1.0; *b*: −0.4; geometric mean of PPV/sensitivity: 0.85). As an example, although incorporation of NAI data slightly increased the accuracy with respect to the unconstrained prediction (PPV: 0.47 for unconstrained, 0.65 for NAI-constrained; sensitivity: 0.54 for unconstrained, 0.66 for NAI-constrained), the NAI-guided prediction resulted in the misfolding of the 3′ domain of the 16S rRNA, while the 2A3-guided prediction correctly recapitulated most of the known base-pairs from the accepted reference structure (PPV: 0.82; sensitivity: 0.90; Figure 4B). We observed the same trend on other cellular RNAs (Supplementary Figures S11 and S12). A similar improvement was observed also when modeling the structure of *B. subtilis* rRNAs (Supplementary Figure S13). Use of RNAstructure (37) rather than ViennaRNA produced similar results (Supplementary Figure S14), hence demonstrating that our conclusions are software-independent.
Characterization of 2A3

Analytical preparations of 2A3 in DMSO unexpectedly revealed that a secondary product was occurring. This reaction proceeded slowly at room temperature after the rapid initial formation of the desired imidazolide, 2A3. The resulting product was a cyclization reaction leading to the formation of 3-azaisatoic anhydride (3AIA). This unwanted side product increased over time, eventually reaching a maximum of ~90% as compared to 2A3 in solution during an overnight reaction in a sealed vessel. The formation of 2A3 proceeds rapidly as CDI is added to the 2-aminonicotinic acid. The conversion of 2A3 to 3AIA then proceeds at room temperature in the crude reaction mixture. The unwanted side reaction proceeds slowly and can be minimized with vigorous stirring under a constant flow of inert gas.

To rule out the possibility that 3AIA rather than 2A3 was acting as an in vivo SHAPE probe, we obtained commercially-available pure 3AIA (Synchem, Germany) and used it to probe living E. coli cells. Notably, 3AIA showed modification frequencies indistinguishable from those of the DMSO control in vivo (Supplementary Figure S15), hence confirming that 2A3 was indeed responsible for the previously observed RNA modification.

To further rule out the possibility that the higher probing efficiencies observed for 2A3 with respect to NAI were due to cell lysis, we incubated HEK293, E. coli and B. subtilis
Figure 3. 2A3 successfully queries regions of the ribosome that are blind to other reagents. (A) Sample of SHAPE–MaP mutation frequencies for all tested compounds across a region spanning nucleotides 990 to 1162 of E. coli 23S rRNA. Colored bases are those whose mutation frequencies exceed by 2-fold the median mutation frequency in the analyzed region. The accepted structure is reported as an arc plot. The hyperreactive residue U1032 and the unreactive stretch of 19 nucleotides are respectively marked in red and blue. (B) Three-dimensional model of the domain depicted in A, colored by B factor (PDB: 5IT8). The inset zooms on the helical region containing the 2A3-hyperreactive residue U1032.
cells with 100 mM 2A3 at 37°C for 30 min. Visual inspection of the HEK293 cells by bright-field microscopy did not reveal any detectable morphological change, nor cell lysis (Supplementary Figure S16A). Similarly, the measured optical density for both E. coli and B. subtilis did not decrease over time, indicating that even after probing for 30 min, cells were still intact (Supplementary Figure S16B, C).

DISCUSSION

We have introduced here 2-aminopyridine-3-carboxylic acid imidazolide (2A3; Figure 5), a novel powerful and accurate SHAPE reagent for the interrogation of RNA structures, both in vitro and in vivo. Briefly, after synthesizing six new candidate SHAPE reagents, we evaluated their ability to modify RNA in cell-free conditions. Although all compounds were able to react with RNA to different extents, four of them (B5, NIC, 6A3 and 2A3) showed partial improvements with respect to NAI. Surprisingly, when tested in vivo, 2A3 significantly outperformed NAI and all the other tested reagents under all the analyzed conditions, with the most striking differences being observed in bacterial cells. Indeed, for both E. coli and B. subtilis, several regions of the ribosome resulted to be blind to probing by NAI and most of the other tested reagents, while they were readily probed by 2A3. In this context, 2A3 better captured local nucleotide dynamics, as confirmed by in depth analysis of available ribosome 3D structures. This reveals that, besides showing a higher ability to react with RNA, 2A3 has also a greater capacity to permeate biological membranes.

It is conceivable that the peptidoglycan of the bacterial cell wall might represent the main limitation when it comes to in vivo SHAPE probing. Indeed, although 2A3 is able to probe both gram-positive and gram-negative bacteria, we observed higher efficiencies in gram-negatives, suggesting that the thicker peptidoglycan of gram-positives limits the permeability to the SHAPE compound. The presence of an amine rather than a methyl group at position C2, that differentiates 2A3 from NAI, might explain this increased permeability, in agreement with a recent study showing that small molecules containing amine groups are more likely to permeate and accumulate into bacteria (38).

Furthermore, we showed that the higher signal-to-noise ratio achieved by 2A3 results in a significantly higher RNA structure prediction accuracy when performing 2A3-informed RNA folding. It is worth noticing that 2A3, as opposed to NAI, outperforms probing with dimethyl sulfate (DMS) as well. Indeed, probing with DMS usually shows a higher signal-to-noise ratio with respect to NAI, hence resulting in more accurate experimentally-informed RNA structure predictions (see for example Figure 3B in (27) and Figure 4A in this work; geometric mean of PPV/sensitivity on E. coli 16S and 23S rRNAs: 0.71 for DMS, 0.67 for NAI) even if providing information on roughly only a half of RNA bases.

Compounds NIC, 2A3 and 6A3 were designed around the nicotinic acid core of NAI, where 2A3 and 6A3 were chosen to be electronically similar but sterically different. The electronic effects predict similar reactivities for 2A3 and 6A3, but the amino group ortho to the activated carbonyl...
in 2A3 is expected to decrease the reactivity due to steric considerations much the way the ortho methyl in NAI decreases the reactivity of NAI relative to NIC. Surprisingly, 2A3 was found to be more reactive than 6A3 as shown by their hydrolysis half-lives (Table S1). It may be that 2A3 falls in a ‘sweet’ spot for reactivity compared to the other tested electrophiles both in vitro and in vivo.

In summary, 2A3 represents a concrete and significant advance in our ability to interrogate RNA structures in living cells. We can anticipate that, being able to readily probe even regions of ribonucleoprotein complexes that are normally hidden to other compounds, 2A3 will rapidly overtake conventional SHAPE reagents, revealing new and previously unobserved features of the in vivo RNA structureome.

DATA AVAILABILITY
SHAPE-MaP data has been deposited to the Gene Expression Omnibus (GEO) database, under the accession GSE154563. Data for ex vivo probing of E. coli RNA with DMSO and NAI has been previously deposited under the accession GSE151327, as part of another study. Additional processed files are available at: http://www.incarnatolab.com/datasets/2A3_Marinus_2020.php.

SUPPLEMENTARY DATA
Supplementary Data are available at NAR Online.

ACKNOWLEDGEMENTS
We would like to acknowledge Prof. Giovanni Maglia (University of Groningen) for critical discussion concerning the design of the new SHAPE compounds.
