The current study analysed the pacing behaviour of athletes competing in the middle-long track event finals of the IAAF Under 18 and Under 20 World Championships between 2015 and 2018. Official finishing times, 1000-m split times and positioning data of 116 female and 153 male athletes, competing in the middle-long distance running (3000 m, 5000 m and 10,000 m) and race walking (5000 m and 10,000 m) events, were gathered. Repeated measures analysis of variance, with 1000-m speed as within-subjects factor and final ranking (medallist, Top 8 or Top 12, rest of the field) as between-subjects factor, was performed to compare the pacing behaviour between athletes. Positioning of the athletes was analysed by Kendall tau-b (Tb) correlation between the intermediate position and final position. Overall, medallists increased their speed throughout a race, with the exception of the 5000 m running event, in which a parabolic pacing behaviour was exhibited. The 1000-m segment in which a significant (P > 0.05) difference in speed was exhibited between differently ranked athletes coincided with a strong (Tb > 0.7) correlation between intermediate and final positioning. These combined results point towards a separation between the athletes during the race, as the Top 8 or Top 12 and the rest of the field are unable to match the speed of the medallists. The distance, discipline, sex, age category and behaviour of competitors all influence the pacing behaviour of young track athletes during international level competition, emphasising the importance and complexity of developing adequate pacing behaviour in track athletes.
competitors (Konings & Hettinga, 2018b; Renfree, Martin, Micklewright, & Gibson, 2014a). The outcome of this decision-making process determines an individual’s behaviour (i.e. pacing behaviour), which is can be quantified by expressing a measure of effort (power output or speed) over segments of the set exercise task (Foster, Schrager, Snyder, & Thompson, 1994). An athlete’s pacing behaviour has been shown to be a decisive feature in athletic performance (Konings & Hettinga, 2018b) and is influenced by a multitude of factors, including the nature of the task (Abbiss & Laursen, 2008; Muehlbauer & Melges, 2011), the characteristics of the athlete (Micklewright, Papadopoulou, Swart, & Noakes, 2010) and the competitive environment (Edwards & Noakes, 2009; Konings & Hettinga, 2018b). The impact of these factors on the pacing behaviour of elite athletes has been thoroughly studied. Within a discipline, the goal (e.g. qualifying for the next round or winning the final) and the importance of the event (e.g. a single world cup competition or the Olympic final) could influence the behaviour of athletes (Hanley & Hettinga, 2018; Konings & Hettinga, 2018a). In championship track athletic races, athletes competing in short-distance events (100 m and 200 m) most frequently exhibit an “all-out” pacing behaviour, in which initial acceleration to near maximal speed is key (Casado, Hanley, Jiménez-Reyes, & Renfree, 2020). Conversely, in the middle-long distance track events (5000 m and 10,000 m), athletes generally exhibit a gradual increase in speed over the race (Hettinga, Edwards, & Hanley, 2019). Additionally, the middle-long distance track athletes who achieved the highest final ranking tend to pace their race differently from the rest of the field (Hettinga et al., 2019). It has been shown that medallists in middle-long distance track races separate themselves from the rest of the field due to their ability to maintain a constant speed or even to increase speed throughout the race (Filipas, La Torre, & Hanley, 2018; Hettinga et al., 2019). Similar pacing behaviour was observed in championship race walking races (over 20-km and 50-km), however, race walkers also need to consider the option to walk in a pack, as it might reduce the chances of attracting the judges’ attention (Hanley, 2013). As for the characteristics of the athlete, previous research has established that the sex and the expertise of an athlete influence the distribution of energy over a single race and over consecutive races (Filipas et al., 2018; Hanley, 2013).

Although the influence of pacing on elite athletic performance in adult athletes has been studied for over 30 years, the way athletes acquire their pacing behaviour has received less attention (Menting, Hendry, Schiphof-Godart, Elferink-Gemser, & Hettinga, 2019). This is remarkable as literature indicates that pacing is not an innate ability, but develops relative to an athlete’s (meta-) cognitive and physical attributes (Micklewright et al., 2012) as well as the experience an athlete has with an exercise task (Foster et al., 2009). Evidence suggests that athletes who develop their pacing behaviour at a younger age achieve better race results during adulthood (Wiersma, Stoter, Visscher, & Hettinga, 2017). Moreover, it has been proposed that the failure to develop adequate pacing behaviour can lead to mismanagement of energy distribution that could result in increased injury and drop-out rates among young athletes (Schiphof-Godart & Hettinga, 2017). Around the age of 10, children are first observed to seemingly reserve their energy to achieve the set exercise. This behaviour further develops during adolescence (Micklewright et al., 2012). Studies in swimming and speed skating found that although pacing behaviour is primarily determined by the characteristics of the task and the characteristics of the athletes, there are distinct differences in pacing behaviour between adolescent and adult athletes (Menting, Elferink-Gemser, Huijgen, & Hettinga, 2019; Menting, Huijgen, Konings, Hettinga, & Elferink-Gemser, 2020; Menting, Konings, Elferink-Gemser, & Hettinga, 2019). For example, although the general pacing behaviour in speed skating is determined by the distance and the discipline (long- or short-track), athletes’ pacing behaviour develops to become more conservative (featuring a slower start and faster finish) throughout adolescence (Menting et al., 2020; Wiersma et al., 2017). Additionally, the development of pacing behaviour towards that of adults seems to commence earlier in female athletes (Menting, Konings, Elferink-Gemser, et al., 2019). Because of the complexity of pacing behaviour development during adolescence, as well as the previously mentioned advantages and risks, coaches are encouraged to monitor the pacing behaviour of developing athletes and compare it against established benchmarks (Menting, Hendry, Schiphof-Godart, et al., 2019). It seems evident that the impact of pacing behaviour development on the path to elite performance should not be underestimated, and insight therein might improve training programmes. Although numerous international level youth sport events which feature reliable performance recording, such as the World Rowing Junior Championships and the World Junior Speed Skating Championships, have been organised for decades, the detailed data recorded during these events are not always publicly available. Even if there is publically available data, the analysis of these data is complicated by the fact that youth...
athletes frequently do not compete in every edition of a championship (Menting et al., 2020). Nevertheless, the analysis of the distribution of effort (e.g. speed) over the duration of a race and the positioning of athletes within a race, based on publically available data from international level youth sports events, has allowed for some of the most rigorous studies on pacing behaviour development in adolescent athletes to date (Menting et al., 2020; Wiersma et al., 2017). These studies form an excellent basis for the creation of informed practical guidelines for the development of pacing behaviour in young athletes (Menting, Hendry, Schiphof-Godart, et al., 2019). However, taking into account the fact that the characteristics of a sport have a large impact on the pacing behaviour of athletes (Mytton et al., 2014), it cannot be taken for granted that the results found in one sport (e.g. speed skating) can be applied to another sport (e.g. track athletics) in an identical fashion. To assist future elite track athletes, it therefore seems essential to have access to research describing the pacing behaviour of young male and female international level athletes competing in specific track athletic events. The current study aims to document the pacing behaviour of young high-standard middle-long distance track athletes during international level championship finals. Previous studies in track athletics have shown that in adult athletes, the athletes who achieved the highest final ranking in the race (e.g. the medallists) determined the pace of the race, hereby influencing the behaviour of the rest of the field (Hettinga et al., 2019). It is therefore hypothesised that alongside the event characteristics (the combination of discipline, race distance and sex), the exhibited pacing behaviour will be linked to the final ranking of the competing athletes.

**Methods**

Official finishing times, 1000-m split times and positional data were gathered from men and women competing in the finals of the middle-long distance running (3000 m, 5000 m and 10,000 m) and race-walking (5000 m and 10,000 m) finals at the International Association of Athletics Federations (IAAF) Under 18 and Under 20 World Championships between 2015 and 2018. The collected data comprises all currently publically available data of athletes competing at Under 18 and Under 20 World Championships. Additional data collection included the date of competition, the date of birth of competing athletes and the temperature during competition. The temperature during the finals was 21.2 ± 3.7°C (14–25°C). All data were obtained from the open-access website of the IAAF (since renamed World Athletics) (http://www.iaaf.org/results) (IAAF, 2019). The study was approved by the local ethics committee and is in accordance with the Declaration of Helsinki. The split times were electronically recorded using transponders fit into the bibs worn by the athletes. Finishing times were recorded using electronic timing devices with an accuracy of a thousandth of a second, as required by the IAAF. Overall, a total of 116 female and 153 male athletes' performances were analysed.

**Data analyses**

The current study was designed as observational research. All collected data were categorised by

</table>
discipline (race walking, running), distance (3000 m, 5000 m and 10,000 m) and sex (female, male). Data of the male 10,000 m race walking event from both U18 and U20 championships were available, therefore, an additional split in age category (U18 & U20) was made for this event. Next, the data were categorised by final ranking: medallists, Top 8 (3000 m & 5000 m) or Top 12 (10,000 m), and the rest of the field. The 1000-m split times were converted to speed to provide a better visual comparison between disciplines and distances. The age of the athletes (Table 1) was calculated by comparing the date of competition with the date of birth of the athlete.

**Statistics**

Data were analysed per discipline, distance, and sex. To analyse the difference in pacing behaviour by ranking, a repeated measures analysis of variance was performed, with the 1000-m speed as a within-subjects factor and the final ranking (medallists, Top 8 or Top 12, rest of the field) as a between-subjects factor. A significant ($P < 0.05$) within-between interaction effect indicates a difference in pacing behaviour between the groups of athletes with differing final rankings. In the analysis of the male 10,000 m race walking events, age category (U18 & U20) was included as additional between-subjects factor, allowing for an examination of the effect of age category on pacing behaviour. For all repeated measures analysis of variance, the effect sizes were calculated using Cohen’s $f$, and categorised as either trivial ($f < 0.1$), medium ($0.1 < f < 0.3$), and large ($f > 0.5$). If a significant difference in pacing behaviour between ranked athletes was found, a multiple comparison post hoc analysis, including Tukey correction, was performed to identify the difference in speed between differently ranked athletes in each individual 1000-m segment of the race. The effect sizes for the differences in speed between ranked athletes were calculated using Cohen’s $d$, and categorised as either trivial ($d < 0.20$), small ($0.21–0.60$), moderate ($0.61–1.20$), large ($1.21–2.00$) or very large ($2.01–4.00$) (Hopkins, Marshall, Batterham, & Hanin, 2009). To analyse the impact of positioning during the race, the relationship between position at 1000-m segments and final position of the athlete (first, second, third, etc.) was analysed by means of a Kendall’s Tau-b ($T_b$) correlation. A positive correlation would indicate that an athlete positioned in the front of the race at a specific 1000-m segment was also among the first to finish. Correlations were perceived as not present/low ($T_b < 0.50$), moderate ($0.50 \leq T_b < 0.70$), or high ($T_b \geq 0.70$), as used in previous research (Konings, Noorbergen, Parry, & Hettinga, 2016; Menting, Konings, Elferink-Gemser, et al., 2019).

**Results**

Finishing times of the athletes in all events, categorised for final ranking, can be found in Table 1. In the male 10,000 m race walking event, a significant interaction effect between age category (U18 vs. U20), final ranking and speed at 1000-m segments, indicating a difference in pacing behaviour between age categories, was found ($F_{8.93, 388.45} = 2.14, P \leq 0.01, \text{large}$). The U18 and U20 male 10,000 m race walking events shall therefore be considered as separate events. A significant interaction effect, indicating a difference in pacing behaviour between athletes categorised by final ranking, was found in all events (Table 1). The speed per 1000-m segment for the male and female running events can be found in Figure 1. The speed per 1000-m segment for the male and female race walking events can be found in Figure 2. The positioning data, describing the correlation between the intermediate position at 1000 m segments and final position, of all events can be found in Figure 3.

**Discussion**

Pacing behaviour is an important element in the development of athletes (Menting, Konings, Elferink-Gemser, et al., 2019). To guide future athletes in developing adequate pac ing behaviour, a better understanding of the pacing behaviour of young athletes is needed (Menting, Konings, Elferink-Gemser, et al., 2019). As pacing behaviour is impacted by the characteristics of the sport performed, race distance and sex of the athletes, these factors should all be taken into account. The aim of the current study was to document the pacing behaviour of young international level track athletes during middle-long distance events. Differences in pacing behaviour were evident between the differently ranked athletes in all analysed events. As hypothesised, higher ranking athletes (medallists and Top 8 or Top 12) generally exhibited a pacing behaviour characterised by an increasing speed, whereas the rest of the field exhibited a decrease in speed over the course of the race. Overall, the pacing behaviour of medallists was characterised by an increase in speed over the course of the race. The exception to this was the 5000 m running event, in which a more parabolic pacing behaviour was exhibited, characterised by a decrease in speed from the start of the race and an increase in speed at the end of the race. The pacing behaviour of the athletes in the Top 8 or Top 12 generally matched the behaviour of the medallists, with differences in speed occurring later in the race. By this point, the athletes in the Top 8 or Top 12 failed to match the speed exhibited by the
medallists. The group of athletes making up the rest of the field exhibited a pacing behaviour characterised by a decrease in speed throughout the race, failing to match the speed of the medallists early on. A similar pattern of pacing behaviour was previously found in adult athletes competing in the 5000 m and 10,000 m running events, whereby the medallists and top eight finishing athletes increased speed during the race, the top 16 athletes demonstrated a constant pace, and the lower-finishing rest of the field showed a decrease in
speed over the course of the race (Filipas et al., 2018). The positioning data provide further insight into the pacing behaviour of the athletes. In all included events, it is evident that the 1000-m segment at which a difference in speed between differently ranked athletes occurs is coinciding with the segment in which there is a strong correlation between intermediate position and final position. This finding provides further evidence that the non-medallists, especially the Top 8 or Top 12 group, match the speed of the medallists for a period of time, during this time the groups of differently ranked athletes exhibit a similar speed and there is a low or medium correlation between intermediate and final positioning. However, eventually the non-medallists are not able to match the speed of the medallists any more, an event marked by a difference in speed between the groups and a high correlation between intermediate and final positioning. The moment in the race at which the speed profiles of medallists start to follow a different trajectory from those of other competitors has previously been termed the separation point (Hettinga et al., 2019). An explanation for the separation of higher-ranked athletes from lower-ranked athletes during a race could be found in differences in physiological capabilities of the athletes, or in factors influencing the decision-making making process of effort regulation during competition. It is possible that the physiological capabilities determining performance in track athletics (such as oxidative capacity) of medallists exceed those of other competitors. This would mean that by keeping up with higher ranking athletes, the lower ranking athletes are performing at an unsustainable level of effort (Filipas et al., 2018). Continuous work at the upper limit of an athletes’ physiological capacity is unsustainable and fatigue will increase rapidly, forcing a decrease in power output in order to prevent lasting damage to the homeostasis (Edwards & Polman, 2012). If the goal of the race was purely to cross the given distance in the shortest time, as is seen in time trial sports, performing for a prolonged duration at the upper limit of an athletes’ performance capacity in the initial section of an exercise task (with a total duration lasting over 120 seconds) generally leads to a sub-optimal performance (Abbiss & Laursen,
However, as middle-long distance track athletics is a head-to-head competition, the goal is to finish before the other athletes in the race, altering the decision-making process regarding the distribution of effort (Konings & Hettinga, 2018a, 2018b). Being in the presence of a direct opponent affords the athlete beneficial effects influencing motivation and opportunities for drafting (Zouhal et al., 2015). Furthermore, in the
discipline of race walking, walking in a pack could reduce the chances of attracting the judges’ attention (Hanley, 2013). Although it has been shown that adult athletes are able to use the presence of an opponent to improve their sports performance (Konings, Schoenmakers, Walker, & Hettinga, 2016), similar results have thus far not been shown in younger individuals (Lambrecht, Rowland, Rowland, & Eston, 2013; Menting, Elferink-Gemser, Edwards, & Hettinga, 2019). It has been proposed that younger individuals are still gathering the necessary experience and developing the required cognitive skillset needed to optimally integrate environmental factors (such as opponents) in their pacing behaviour (Menting, Elferink-Gemser, Edwards, et al., 2019; Menting, Konings, Elferink-Gemser, et al., 2019). It could therefore be difficult for younger athletes to optimally navigate the complex decision-making making process regarding effort distribution during competition.

The inclusion of similar events in male and female athletes in the current study provides the opportunity to compare the pacing behaviour between sexes. Comparing the pacing behaviour exhibited by male and female athletes in the 3000 m and 5000 m running events, it was evident that the separation point between the differently ranked athletes occurred earlier on in the male event, compared to female event. On first glance, these findings seem to contradict a previous study in elite adults athletes which concluded that, in the 5000 m events, female medallists separate themselves at an earlier stage of the race, between 2000 and 3000 m, and male medallists differentiate themselves from the rest of the field after 4000 m (Hettinga et al., 2019). However, it has previously been suggested that the development of pacing behaviour differs between male and female athletes (Deaner & Lowen, 2016; Menting, Konings, Elferink-Gemser, et al., 2019), with girls experiencing growth spurt-related physical changes and development of the prefrontal cortical functioning, at an earlier age (Blakemore, Burnett, & Dahl, 2010; Malina & Bouchard, 2004). The change in cognitive development and maturation of the musculoskeletal system could be the reason for the difference in pacing behaviour exhibited by male and female athletes in the observed races (Elferink-Gemser & Hettinga, 2017; Menting, Konings, Elferink-Gemser, et al., 2019), however, more extensive research is needed.

Notwithstanding the fact that this study is a response to the need for more sport-specific literature on the pacing behaviour of young athletes (Elferink-Gemser & Hettinga, 2017; Menting, Hendry, Schiphof-Godart, et al., 2019), some limitations should be addressed. Although this study includes all currently available data of youth athletes performing at international underage championships, only data of athletes performing in a limited number of races (all finals of a championships) were available. The use of a limited number of races provides the disadvantage of not having the possibility to account for inter-race variability, which decreases the generalisation of the findings. However, the examination of a small number of races, including singles races, has previously been shown to provide valuable new insights into the behaviour of athletes in endurance athletic events (Renfree & Gibson, 2013; Renfree, Mytton, Skorski, & Gibson, 2014b). In this trend, the current study provides novel insights into the behaviour of young (U18 and U20) middle-long distance track athletes. It should nevertheless be mentioned that the use of larger datasets, including data from more athletes, over more years, and from different stages of competition (e.g. heats and semi-finals), has provided valuable information regarding the pacing behaviour of athletes in other sports such as short-track speed skating (Konings & Hettinga, 2018a; Menting et al., 2020). Access to data from a larger number of athletes, made publicly available by the IAAF or collected with the permission of the athletes, would provide the opportunity to expand on the novel findings of the current study. Secondly, the resolution of the publicly available data from athletes performing in the IAAF Under 18 and Under 20 World Championships was low when compared data used to previous studies (Hettinga et al., 2019; Thiel, Foster, Banzer, & De Koning, 2012). Using data with a higher resolution will allow for a more detailed description of the variation in speed over the course of the race, and therefore a more detailed description of an athletes’ pacing behaviour (Thiel et al., 2012). The gathering of higher resolution data has previously been achieved through a collaboration with official timing companies linked to athletic events or the use of video recording (Hettinga et al., 2019; Mytton, Archer, Thompson, Renfree, & Gibson, 2013). Lastly, to properly study the development of pacing behaviour during adolescence, a longitudinal design, following athletes throughout adolescence and controlling for each athletes’ sport specific experience, is desirable (Elferink-Gemser, Wierike, & Visscher, 2018; Menting et al., 2020). Future research, featuring a longitudinal design, higher resolution data from a larger number of athletes and the inclusion of different stages of competition should be conducted to further our understanding of the development of young track athletes.

Conclusion

The current study analysed the pacing behaviour of athletes performing in international U18 and U20 middle-long distance track athletic finals. The pacing behaviour of these athletes is linked to the athletes’ final ranking in
the race. The highest ranking athletes (the medallists) increased their speed throughout the race. Over the course of the race, the other athletes failed to match the speed of the medallists, likely causing a separation between the higher and lower ranking athletes. The distance at which athletes exhibit a failure to match the speed of the medallists differentiates the Top 8 or Top 12 athletes (late separation from medallists) and the rest of the field (early separation from medallists). The differences in pacing behaviour between young track athletes of different sexes competing in the same event, fit the current general knowledge regarding pacing behaviour development of youth athletes. However, more extensive longitudinal research is needed to provide further details of the development of pacing behaviour in track athletics.
