Abstract. Multistage problems with uncertain parameters and integer decisions variables are among the most difficult applications of robust optimization (RO). The challenge in these problems is to find optimal here-and-now decisions, taking into account that the wait-and-see decisions have to adapt to the revealed values of the uncertain parameters. An existing approach to solve these problems is to construct piecewise constant decision rules by adaptively partitioning the uncertainty set. The partitions of this set are iteratively updated by separating so-called critical scenarios, and methods for identifying these critical scenarios are available. However, these methods are most suitable for problems with continuous decision variables and many uncertain constraints, providing no mathematically rigorous methodology for partitioning in case of integer decisions. In particular, they are not able to identify sets of critical scenarios for integer problems with uncertainty in the objective function only. In this paper, we address this shortcoming by introducing a general critical scenario detection method. The new method leverages the information embedded in the dual vectors of the LP relaxations at the nodes of the branch-and-bound tree used to solve the corresponding static problem. Numerical experiments on a route planning problem show that our general-purpose method outperforms a problem-specific approach from the literature.

Keywords: robust optimization • adjustability • adaptivity • mixed-integer

1. Introduction

Robust optimization (Ben-Tal et al. 2009) is a paradigm for dealing with uncertainty in mathematical optimization problems where the objective function is minimized under the assumption that the uncertain parameters attain their worst-case value from an uncertainty set—that is, a set of likely values. This methodology has found a wide range of applications; see, for example, inventory management (Ben-Tal et al. 2004), facility location (Ordonez and Zhao 2007), network design (Atamtürk and Zhang 2007), finance (Fabozzi et al. 2010), and many others. For a broad overview of applications of robust optimization (RO), we refer the reader to Gabrel et al. (2014).

An important class of RO problems are multi-stage problems where here-and-now decisions are implemented before (some of) the uncertain parameters are revealed, and wait-and-see decisions are made when these uncertain parameters are known. The wait-and-see decisions will typically differ for different realizations of the uncertain parameters

and this is why we call them adjustable decisions. In general, such adjustable problems are $\mathcal{NP}$ -hard (Ben-Tal et al. 2009), even for problems with continuous decision variables only, and thus require good suboptimal but tractable solutions. For this reason, Ben-Tal et al. (2004) propose to formulate the later-stage decisions as affine functions of the uncertain parameters. Their approach has later been extended to other function classes; see, for example, Chen and Zhang (2009) and Bertsimas et al. (2011). An alternative solution method that bypasses the need for decision rules is to use Fourier–Motzkin elimination to remove the later-stage decisions from the problem formulation (Zhen et al. 2018).

Incorporating adjustable decisions in RO problems becomes more challenging if (some of) the decisions are restricted to be integer. In this case, it becomes difficult to formulate these decisions as tractable functions of the uncertain parameters. First attempts to address this difficulty include Bertsimas and Caramanis (2007), who construct rounding-based decision rules

based on sampling that are feasible with high probability, and Vayanos et al. (2011), who partition the uncertainty set ex ante into small subsets with different decisions each.

In the current literature, we distinguish three systematic approaches for designing integer decision rules for mixed-integer adjustable RO problems. The first is to use piecewise linear decision rules for both continuous and binary decision variables, proposed by Bertsimas and Georghiou (2015). They formulate the decision rules as differences of two convex functions, and for binary variables the value 0 is implemented if the decision rule is positive, and the value 1, otherwise. In a related fashion, the decisions in the approach of Bertsimas and Georghiou (2017) are affine transformations of multiple indicator functions of half-spaces in the space of uncertain parameters.

The second approach is the K -adaptability (Bertsimas and Caramanis 2010), proposed in the integer context by Hanasusanto et al. (2015). In this approach, K possible values for the adjustable decisions are selected here-and-now, and for each outcome of the uncertain parameters the best out of these K possible values will be selected for the wait-and-see decisions. The corresponding optimization problem is solved by reformulating it as a static mixed-integer RO problem. This approach was extended by Subramanyam et al. (2017), who allow discrete uncertain parameters and develop a branch-and-bound algorithm for the K -adaptable problem.

The third approach is the splitting methodology proposed by Postek and den Hertog (2016) and Bertsimas and Dunning (2016); the latter use the term “partitioning” instead of “splitting.” In this approach, the uncertainty set is iteratively split into smaller subsets. For each subset, a possibly different value for the adjustable decisions is selected that will be implemented if the uncertain parameter turns out to be in that subset. The uncertainty set is heuristically split based on *critical scenarios* of the uncertain parameters, since the theory for detecting these critical scenarios shows that if they are not separated from each other, the objective value of the solution induced by the split uncertainty set cannot improve. This theory, however, only holds for problems with continuous decision variables, and can only be heuristically applied to some mixed-integer problems. In particular, for mixed-integer adjustable RO problems with uncertainty in the objective function only, this theory is unable to detect critical scenarios that need to be split.

We address exactly this shortcoming by detecting critical scenarios in mixed-integer adjustable RO problems. In fact, we show that these scenarios can be obtained from the optimal dual solutions of the LP relaxations in a specific set of nodes in the B&B tree

(see, e.g., Schrijver 1986) used to solve the corresponding static mixed-integer RO problem. This means that these scenarios can be obtained as by-product when solving the static mixed-integer RO problem.

In this paper, we only present our critical scenario detection method for *two-stage* mixed-integer adjustable RO problems for ease of exposition. However, similarly as in Postek and den Hertog (2016) and Bertsimas and Dunning (2016), it can easily be extended to the multistage case by enforcing the non-anticipativity constraints.

The main contributions of our paper are as follows:

- we detect critical scenarios in mixed-integer adjustable RO problems, extending the theory of Postek and den Hertog (2016) and Bertsimas and Dunning (2016);
- we derive an optimality criterion for our splitting methodology, proving when the uncertainty set requires no more partitioning;
- we show using numerical experiments on a route planning problem that our general-purpose critical scenario detection method outperforms the problem-specific heuristic developed in Postek and den Hertog (2016).

The remainder of this paper is organized as follows. In Section 2 we review the splitting methodology of Postek and den Hertog (2016) and Bertsimas and Dunning (2016). In Section 3 we derive our critical scenario detection method. In Section 4 we illustrate our method using numerical experiments on a route planning problem, and we end with conclusions in Section 5.

2. Splitting Methodology for Mixed-Integer Adjustable RO Problems

We consider the mixed-integer adjustable RO problem:

$$\begin{aligned} \bar{t} := \min_{t, x, y(z)} \quad & t \\ \text{s.t. } \quad & t - c(z)^\top x - q(z)^\top y(z) \geq 0 \quad \forall z \in Z \\ & a_i(z)^\top x + w_i(z)^\top y(z) \geq b_i \quad \forall z \in Z \quad \forall i \in \mathcal{I} \\ & x \in X, \quad y(z) \in Y \quad \forall z \in Z, \end{aligned} \tag{ARO}$$

where the uncertainty is in both the cost parameters $c(z)$, $q(z)$ and the constraint coefficients $a_i(z)$, $w_i(z)$, $i \in \mathcal{I}$, with z representing the uncertain parameters in the model and Z a polyhedral uncertainty set defined by $Z = \{z \in \mathbb{R}^L : Pz \leq p\}$, and the sets X and Y represent nonnegativity and integer restrictions. In this problem the decisions $x \in \mathbb{R}^{d_1}$ have to be determined *before* the value of the uncertain parameter z is known, whereas decisions $y(z) \in \mathbb{R}^{d_2}$ are made after the realizations of z are revealed. We assume w.l.o.g. that the first m_1 and m_2 components of the decision vectors x and $y(z)$, respectively, are restricted to be integer.

Thus, $X = \mathbb{Z}_+^{m_1} \times \mathbb{R}_+^{d_1-m_1}$ and $Y = \mathbb{Z}_+^{m_2} \times \mathbb{R}_+^{d_2-m_2}$. Moreover, we make the following assumptions with respect to the uncertainty set Z and the parameters in the model.

Assumption 1. The polyhedral uncertainty set Z is non-empty and bounded.

Assumption 2. All parameters $c(z)$, $q(z)$, $a_i(z)$ and $w_i(z)$ are affine in the uncertain parameter z . That is, $c(z) = \bar{c} + Cz$, $q(z) = \bar{q} + Qz$, $a_i(z) = \bar{a}_i + A_i z$, and $w_i(z) = \bar{w}_i + W_i z$, where $\bar{c}, \bar{a}_i \in \mathbb{R}^{d_1}$ and $\bar{q}, \bar{w}_i \in \mathbb{R}^{d_2}$ represent the nominal values and $C, A_i \in \mathbb{R}^{d_1 \times L}$ and $Q, W_i \in \mathbb{R}^{d_2 \times L}$. $\square$

Ben-Tal et al. (2009) show that the adjustable optimization problem is NP-hard, even when all decision variables are continuous. For this reason, a typical approach to simplify such problems is to restrict $y(z)$ to a particular class of functions. For example, Ben-Tal et al. (2004) propose so-called affine decision rules, meaning that $y(z)$ is an affine function of z . The problem with this approach in our setting is that affine decision rules lead to infeasible second-stage decisions if some of these decisions are restricted to be integer.

Instead, we follow the approach of Postek and den Hertog (2016) and Bertsimas and Dunning (2016), and construct piecewise constant decision rules for mixed-integer adjustable RO problems by splitting the uncertainty set. After r rounds of iterative splitting we obtain a partition $\mathcal{Z}_r$ of Z given by $\mathcal{Z}_r = \{Z_{r,s}, s \in \mathcal{S}_r\}$, where $Z_{r,s}$ are nonempty polyhedral subsets of Z with mutually disjoint interiors and such that $\bigcup_{s \in \mathcal{S}_r} Z_{r,s} = Z$. A piecewise constant decision rule can now be obtained by assuming that for each $s \in \mathcal{S}_r$, we will select the same second-stage decision $y^{r,s}$ for each $z \in \text{int}(Z_{r,s})$. That is, for all $z \in Z$,

$$y(z) = y^{r,s} \quad \text{if } z \in \text{int}(Z_{r,s}).$$

If z belongs to the boundary of possibly multiple subsets $Z_{r,s}$, then all corresponding decisions $y^{r,s}$ can in principle be implemented. We assume that one of these decisions is selected arbitrarily. Under this assumption, the mixed-integer adjustable RO problem (ARO) reduces to

$$\begin{aligned} \bar{t}^r := \min_{t^r, x^r, y^{r,s}} \quad & t^r \\ \text{s.t. } \quad & t^r - c(z)^T x^r - q(z)^T y^{r,s} \geq 0 \\ & \forall z \in Z_{r,s} \quad \forall s \in \mathcal{S}_r \\ & a_i(z)^T x^r + w_i(z)^T y^{r,s} \geq b_i \\ & \forall z \in Z_{r,s} \quad \forall i \in \mathcal{I}, \quad \forall s \in \mathcal{S}_r \\ & x \in X, \quad y^{r,s} \in Y \quad \forall s \in \mathcal{S}_r, \end{aligned} \quad (\text{RO}_r)$$

where $Z_{r,s} = \{z \in \mathbb{R}^L : p^{r,s} z \leq p^{r,s}\}$ for all $s \in \mathcal{S}_r$. That is, we assume that the subsets $Z_{r,s}$ are separated

from each other by hyperplanes. Note that the left-hand sides of the constraints in (RO_r) are continuous in z , so that we may replace $Z_{r,s}$ by $\text{int}(Z_{r,s})$ and vice versa.

The problem (RO_r) is a static mixed-integer RO problem in which all decisions—that is, x^r and $y^{r,s}$, $s \in \mathcal{S}_r$ —have to be determined before the uncertain parameter z is known. The robust counterpart (Ben-Tal et al. 2009) of this problem is a deterministic MILP that can be solved, for example, by branch-and-bound. Clearly, by iteratively splitting the uncertainty sets $Z_{r,s}$, the approximation (RO_r) of the mixed-integer adjustable RO problem (ARO) iteratively improves. In fact, Bertsimas and Caramanis (2010) show that under mild conditions (RO_r) converges to (ARO) if the maximum diameter of any uncertainty set $Z_{r,s}$ in the partition $\mathcal{Z}_r$ converges to zero.

Our contribution is that we determine how to iteratively split the uncertainty sets. This is a generalization of the results of Postek and den Hertog (2016) for the case in which all decision variables are continuous. In this case, they detect a finite set $\bar{Z}_{r,s}$ of critical scenarios for each uncertainty subset $Z_{r,s}$, $s \in \mathcal{S}_r$, after each splitting round r . Critical scenarios are the uncertainty realizations $\bar{z}_{r,s}$ that determine the objective function value of (RO_r) . That is, in (RO_r) , the uncertainty subset $Z_{r,s}$ can be replaced by the corresponding set of critical scenarios $\bar{Z}_{r,s}$ without affecting the optimal objective value. In problems with continuous decision variables only, the critical scenarios correspond to uncertainty realizations $\bar{z}_{r,s}$ that make constraints active. Postek and den Hertog (2016) show that if none of these sets $\bar{Z}_{r,s}$ of critical scenarios are split in round $r+1$, then $\bar{t}^{r+1} = \bar{t}^r$ (i.e., the worst-case objective value does not decrease); see Theorem 1 in Postek and den Hertog (2016). This provides a theoretical justification for splitting the sets $\bar{Z}_{r,s}$ of critical scenarios.

The theoretical result, however, does not hold when some of the decision variables in the model are restricted to be integer. Therefore, Postek and den Hertog (2016) propose to use the critical scenarios $\bar{Z}_{r,s}$ of the LP relaxation of (RO_r) . However, in general this approach does not work. For example, if there is only uncertainty in the cost parameters $c(z)$ and $q(z)$, then the LP relaxation may only find a single critical scenario $\bar{z}_{r,s}$ per uncertainty subset $Z_{r,s}$, giving us no indication on how to split these sets. Also in Example 1 below with uncertainty in the constraints, the LP-relaxation only finds a single critical scenario.

Example 1. In Figure 1 we graphically illustrate why it may be insufficient to use only the critical scenarios of the LP relaxation of (RO_r) . For convenience, we assume that $r=0$, meaning that the uncertainty set Z has not been split yet.

Figure 1. Illustration of the Difference Between Detecting Critical Scenarios in the Continuous (Left) and Integer Case with B&B (Right)

In this example, we assume that there are only two adjustable decision variables, y_1 and y_2 (there are no first-stage decisions x), both of which are integer. Moreover, we assume that there is no uncertainty in the cost parameters $q(z)$. Thus, only the feasible region of this problem depends on the uncertain parameter z . In Figure 1, the constraint sets corresponding to scenarios $\bar{z}^1$ and $\bar{z}^2$, respectively, are represented by the two quadrilaterals.

In the left-hand panel, the feasible region of the LP relaxation of (RO_0) is depicted as the shaded intersection of the two quadrilaterals. At the optimal solution $(1.25, 1.5)$, only the constraints corresponding to scenario $\bar{z}^2$ are active, and thus $\bar{z}^2$ is the only critical scenario. Notice that without the constraints corresponding to $\bar{z}^1$, the same solution would be optimal, and thus the worst-case objective function of (ARO) will not improve if we are allowed to make different (continuous) decisions y_1 and y_2 for the different scenarios $\bar{z}^1$ and $\bar{z}^2$. Therefore, $\bar{z}^1$ is a single critical scenario for the LP-relaxation of (RO_0) .

In the right-hand panel, we consider the integer RO problem (RO_0) . Its feasible region consists of all integer points in the intersection of the two quadrilaterals with optimal solution $(2, 2)$.

If we would classify $\bar{z}^1$ as the only critical scenario of this problem, then the optimal solution to the integer problem with only this single scenario $\bar{z}^1$, in which the feasible region consists of all integer points within the quadrilateral corresponding to $\bar{z}^1$, should be the same as for the integer problem with both scenarios $\bar{z}^1$ and $\bar{z}^2$ included. In the latter case, the feasible region consists of all integer points within *both* quadrilaterals. Clearly, this is not true since the optimal solution in the first case is $(2, 1)$, which has a better objective value than the optimal solution in the problem with both scenarios— $(2, 2)$. A similar argument applies to the case in which $\bar{z}^2$ would be classified as the only critical scenario. Thus, both scenarios $\bar{z}^1$ and $\bar{z}^2$ jointly determine that the optimal

solution to (RO_0) is $(2, 2)$ and thus both are critical scenarios.

Since there are two critical scenarios here, it is possible to improve the worst-case objective value of (ARO) by separating scenarios $\bar{z}^1$ and $\bar{z}^2$ and thus making different decisions (y_1^1, y_2^1) and (y_1^2, y_2^2) for the scenarios $\bar{z}^1$ and $\bar{z}^2$. Each decision needs to satisfy only the constraints of the corresponding scenario—that is, belong to the corresponding quadrilateral. Such a pair of decisions is given by $(y_1^1, y_2^1) = (1, 2)$ and $(y_1^2, y_2^2) = (2, 1)$, both with smaller objective function values than $(2, 2)$. $\square$

In this paper, we propose a general approach for detecting sets $\bar{Z}_{r,s}$ of critical scenarios in adjustable RO problems with integer decision variables. In fact, we show that information about the critical scenarios is embedded in the dual solutions of the nodes in the B&B tree used to solve the static mixed-integer problem (RO_r) , which will be the basis of our scenario detection method. In Section 3 we discuss the theory behind our approach.

Throughout the remainder of this paper we make the following mild assumption.

Assumption 3. The problem (RO_0) is feasible and the feasible region of its LP relaxation is nonempty and bounded.

3. Critical Scenario Detection Using B&B

In this section we show how to detect critical scenarios $\bar{Z}_{r,s}$ for the static mixed-integer RO problem (RO_r) after r splitting rounds. Let $\bar{t}^{r,n}$ denote the objective value at each node $n \in \mathcal{N}_r$ of the B&B tree used to solve (RO_r) . We will show that we can use the optimal dual variables at each node $n \in \mathcal{N}_r$ with $\bar{t}^{r,n} \geq \bar{t}^r$ to construct sets of critical scenarios $\bar{Z}_{r,s}$. In fact, we will show that it suffices to only consider nodes n in a so-called *critical cutset* $\mathcal{C}_r$ of the B&B tree. This is the smallest set of nodes with $\bar{t}^{r,n} \geq \bar{t}^r$ that separates the root node from the leaf nodes Λ_r in the B&B tree; see Figure 2.

Figure 2. An Example of a Critical Cutset Set $\mathcal{O}_r = \{1, 3, 4\}$ (in Gray) of Nodes in a B&B Tree

Definition 1. Let $\mathcal{N}_r$ denote the nodes of the B&B tree used to solve (RO_r) . Then, $\mathcal{O}_r \subset \mathcal{N}_r$ is called a *critical cutset* of the B&B tree if

- i. $\bar{t}^{r,n} \geq \bar{t}^r$ for all $n \in \mathcal{O}_r$, and
- ii. $\mathcal{O}_r \cap \Pi(n) \neq \emptyset$ for all $n \in \Lambda_r$,

where $\Pi(n)$ represents the path from the root node to the leaf node $n \in \Lambda_r$ in the B&B tree. $\square$

Remark 1. To identify the nodes in the critical cutset $\mathcal{O}_r$, we first solve (RO_r) to optimality using B&B, yielding the optimal objective value $\bar{t}^r$. Next, we go through the B&B tree a second time to find nodes n with $\bar{t}^{r,n} \geq \bar{t}^r$.

In Section 3.1 we construct the primal and dual LPs corresponding to each node $n \in \mathcal{N}_r$ of the B&B tree, and we show that for each node n strong LP duality holds. In Section 3.2 we use the optimal dual variables of nodes $n \in \mathcal{O}_r$ in a critical cutset to construct sets of critical scenarios $\bar{Z}_{r,s}$, and we prove that if these sets are not split after round r' , then the worst-case objective value does not improve and thus $\bar{t}^{r'} = \bar{t}^r$ for $r' \geq r$.

3.1. Strong LP Duality at B&B Nodes

At each node $n \in \mathcal{N}_r$ of the B&B tree used to solve (RO_r) , we solve the LP relaxation of (RO_r) with several additional branching constraints on x^r and $y^{r,s}$. The problem that we solve at the n -th node of the tree equals

$$\begin{aligned}
 \bar{t}^{r,n} := \min_{t^{r,n}, x^{r,n}, y^{r,n,s}} t^{r,n} \quad & (\text{RO}_{r,n}) \\
 \text{s.t. } t^{r,n} - c(z)^\top x^{r,n} - q(z)^\top y^{r,n,s} & \geq 0 \\
 & \forall z \in Z_{r,s} \quad \forall s \in \mathcal{S}_r \\
 a_i(z)^\top x^{r,n} + w_i(z)^\top y^{r,n,s} & \geq b_i \\
 & \forall z \in Z_{r,s}, \quad \forall i \in \mathcal{I}, \quad \forall s \in \mathcal{S}_r \\
 (d_j^{r,n})^\top x^{r,n} + \sum_{s \in \mathcal{S}_r} (e_j^{r,n,s})^\top y^{r,n,s} & \geq \delta_j^{r,n} \\
 & \forall j \in \mathcal{J}_{r,n} \\
 x^{r,n} \geq 0, y^{r,n,s} \geq 0 & \quad \forall s \in \mathcal{S}_r,
 \end{aligned}$$

where the last constraints represent the branching constraints, indexed by $j \in \mathcal{J}_{r,n}$.

Remark 2. We present the branching constraints in $(\text{RO}_{r,n})$ in such a general form since our results also hold in the more general framework of disjunctive programming. However, we prefer to present our results in the context of B&B. Thus, the vectors of coefficients $d_j^{r,n}$ and $e_j^{r,n,s}$ may be interpreted as either positive or negative unit vectors, or zero. In fact, in the context of B&B there is at most one vector $d_j^{r,n}$ or $e_j^{r,n,s}$ nonzero for each $j \in \mathcal{J}_{r,n}$. $\square$

Problem $(\text{RO}_{r,n})$ is not a standard LP since it has infinitely many constraints. However, since Z is a non-empty and bounded polyhedron by Assumption 2, we are able to derive its robust counterpart (Ben-Tal et al. 2009):

$$\begin{aligned}
 \bar{t}^{r,n} = \min_{t^{r,n}, x^{r,n}, y^{r,n,s}, \kappa_i^{r,n,s}} t^{r,n} \quad & (\text{P-RC}_{r,n}) \\
 \text{s.t. } t^{r,n} - \bar{c}^\top x^{r,n} - \bar{q}^\top y^{r,n,s} - (p^{r,s})^\top \kappa_0^{r,n,s} & \geq 0 \\
 & \forall s \in \mathcal{S}_r \\
 \bar{a}_i^\top x^{r,n} + \bar{w}_i^\top y^{r,n,s} - (p^{r,s})^\top \kappa_i^{r,n,s} & \geq b_i \\
 & \forall i \in \mathcal{I}, \quad \forall s \in \mathcal{S}_r \\
 (d_j^{r,n})^\top x^{r,n} + \sum_{s \in \mathcal{S}_r} (e_j^{r,n,s})^\top y^{r,n,s} & \geq \delta_j^{r,n} \\
 & \forall j \in \mathcal{J}_{r,n} \\
 C^\top x^{r,n} + Q^\top y^{r,n,s} - (P^{r,s})^\top \kappa_0^{r,n,s} & = 0 \\
 & \forall s \in \mathcal{S}_r \\
 A_i^\top x^{r,n} + W_i^\top y^{r,n,s} + (P^{r,s})^\top \kappa_i^{r,n,s} & = 0 \\
 & \forall i \in \mathcal{I}, \quad \forall s \in \mathcal{S}_r \\
 x^{r,n} \geq 0, y^{r,n,s} \geq 0, \kappa_i^{r,n,s} \geq 0 & \\
 & \forall i \in \mathcal{I} \cup \{0\}, \quad \forall s \in \mathcal{S}_r,
 \end{aligned}$$

where $\kappa_i^{r,n,s}$, $i \in \mathcal{I} \cup \{0\}$ represent additional variables required to move from robust constraints in $(\text{RO}_{r,n})$,

that hold for all $z \in Z_{r,s}$ to their robust counterparts in $(P-RC_{r,n})$. This robust counterpart is an LP since $Z_{r,s}$ is a nonempty polyhedral uncertainty set for every $s \in \mathcal{S}_r$, and its dual is given by

$$\begin{aligned}
 & \max_{\lambda_i^{r,n,s}, \mu_j^{r,n,s}} \sum_{s \in \mathcal{S}_r} \sum_{i \in \mathcal{I}} \lambda_i^{r,n,s} b_i + \sum_{j \in \mathcal{J}_{r,n}} \mu_j^{r,n} \delta_j^{r,n} \quad (D-RC_{r,n}) \\
 & \text{s.t.} \quad \sum_{s \in \mathcal{S}_r} \lambda_0^{r,n,s} = 1 \\
 & \quad \sum_{s \in \mathcal{S}_r} (\lambda_0^{r,n,s} \bar{c} + C u_0^{r,n,s}) - \sum_{i \in \mathcal{I}} \sum_{s \in \mathcal{S}_r} (\lambda_i^{r,n,s} \bar{a}_i + A_i u_i^{r,n,s}) \\
 & \quad - \sum_{j \in \mathcal{J}_{r,n}} \mu_j^{r,n} d_j^{r,n} \geq 0 \\
 & \quad \lambda_0^{r,n,s} \bar{q} + Q u_0^{r,n,s} - \sum_{i \in \mathcal{I}} (\lambda_i^{r,n,s} \bar{w}_i + W_i u_i^{r,n,s}) \\
 & \quad - \sum_{j \in \mathcal{J}_{r,n}} \mu_j^{r,n} e_j^{r,n,s} \geq 0, \quad \forall s \in \mathcal{S}_r \\
 & \quad p^{r,s} u_i^{r,n,s} \leq \lambda_i^{r,n,s} p^{r,s}, \quad \forall i \in \mathcal{I} \cup \{0\}, \\
 & \quad \quad \quad \forall s \in \mathcal{S}_r \\
 & \quad \lambda_i^{r,n,s} \geq 0, \mu_j^{r,n,s} \geq 0, \quad \forall i \in \mathcal{I} \cup \{0\}, \\
 & \quad \quad \quad \forall j \in \mathcal{J}_{r,n}, \quad \forall s \in \mathcal{S}_r.
 \end{aligned}$$

Proposition 1. Under Assumptions 1–3, strong LP duality holds between $(P-RC_{r,n})$ and $(D-RC_{r,n})$ for each node $n \in \mathcal{N}_r$ of the B&B tree after splitting round r .

Proof. Problems $(P-RC_{r,n})$ and $(D-RC_{r,n})$ form a standard primal dual pair. From LP duality theory (see, e.g., Schrijver 1986), it follows that strong LP duality holds unless both the primal and dual problem are infeasible. Thus, to prove the claim, it suffices to show that either the primal or dual is feasible.

Consider the static mixed-integer RO problem (RO_r) with $r = 0$. By Assumption 3 this problem is feasible, and the feasible region of its LP-relaxation is nonempty and bounded. The LP relaxation can be interpreted as $(RO_{r,n})$ with $r = 0$ and $n = 0$ the root node of the B&B tree used to solve (RO_0) . Hence, under Assumption 3, $(P-RC_{0,0})$ has a nonempty, bounded feasible region and thus a finite objective value. By strong LP duality, the objective value of $(D-RC_{0,0})$ is also finite and its feasible region thus nonempty.

Using the same arguments as above, $(D-RC_{r,n})$ is feasible at the root node $n = 0$ for any splitting round r , since (RO_r) is feasible because the feasible solution for (RO_0) can be implemented for (RO_r) after r splitting rounds using the same y -values for all uncertainty subsets $s \in \mathcal{S}_r$ as in (RO_0) . Moreover, the additional branching constraints in $(P-RC_{r,n})$ for arbitrary n restrict the primal feasible region, but enlarge the dual feasible region. Hence, $(D-RC_{r,n})$ is feasible for any r

and n , and thus strong LP duality between $(P-RC_{r,n})$ and $(D-RC_{r,n})$ always holds. $\square$

3.2. Critical Scenarios

Next, we discuss how to obtain critical scenarios from the dual variables of $(D-RC_{r,n})$. Recall that $Z_{r,s} = \{z : p^{r,s} z \leq p^{r,s}\}$ and that the optimal dual variables $(\bar{\lambda}, \bar{\mu}, \bar{\mu})$ of $(D-RC_{r,n})$ satisfy $p^{r,s} \bar{u}_i^{r,n,s} \leq \bar{\lambda}_i^{r,n,s} p^{r,s}$ for $i \in \mathcal{I} \cup \{0\}$. Hence, if $\bar{\lambda}_i^{r,n,s} > 0$, then

$$p^{r,s} (\bar{u}_i^{r,n,s} / \bar{\lambda}_i^{r,n,s}) \leq p^{r,s} \Rightarrow (\bar{u}_i^{r,n,s} / \bar{\lambda}_i^{r,n,s}) \in Z_{r,s}.$$

That is, the quotient $\bar{u}_i^{r,n,s} / \bar{\lambda}_i^{r,n,s}$ can be interpreted as a scenario from the uncertainty set $Z_{r,s}$. The set of all $\bar{u}_i^{r,n,s} / \bar{\lambda}_i^{r,n,s}$ for which $\bar{\lambda}_i^{r,n,s} > 0$, $i \in \mathcal{I} \cup \{0\}$, will represent the set of critical scenarios $\bar{Z}_{r,n,s}$ in node n corresponding to the uncertainty subset $Z_{r,s}$. However, we need to take into account the possibility that problem $(P-RC_{r,n})$ is infeasible and problem $(D-RC_{r,n})$ is unbounded, and thus no optimal dual solution exists. For this reason, we call any solution $(\bar{\lambda}, \bar{\mu}, \bar{\mu})$ optimal if its corresponding objective value in $(D-RC_{r,n})$ exceeds $\bar{t}^r$.

Definition 2. For every node $n \in \mathcal{C}_r$ in a critical cutset of the nodes of the B&B tree used for solving the static mixed-integer RO problem (RO_r) , we call $(\bar{\lambda}, \bar{\mu}, \bar{\mu})$ an optimal solution of $(D-RC_{r,n})$ if $(\bar{\lambda}, \bar{\mu}, \bar{\mu})$ is feasible and its objective value exceeds $\bar{t}^r$.

Definition 3. Let the splitting round r be given, and let $\mathcal{C}_r \subset \mathcal{N}_r$ be a critical cutset of the nodes of the B&B tree used to solve the static mixed-integer RO problem (RO_r) . Then, for each $n \in \mathcal{C}_r$ and $s \in \mathcal{S}_r$, the set of critical scenarios $\bar{Z}_{r,n,s}$ corresponding to uncertainty subset $Z_{r,s}$ in node n is given by

$$\bar{Z}_{r,n,s} = \{\bar{u}_i^{r,n,s} / \bar{\lambda}_i^{r,n,s} : \bar{\lambda}_i^{r,n,s} > 0, i \in \mathcal{I} \cup \{0\}\}.$$

Moreover, the set of critical scenarios $\bar{Z}_{r,s}$ corresponding to the uncertainty subset $Z_{r,s}$, $s \in \mathcal{S}_r$, is

$$\bar{Z}_{r,s} = \bigcup_{n \in \mathcal{C}_r} \bar{Z}_{r,n,s}.$$

Now we are ready to prove our main theorem, which can be interpreted as the integer analogue of Theorem 1 in Postek and den Hertog (2016).

Theorem 1. Consider the static mixed-integer RO problem (RO_r) under Assumptions 1–3, and assume that we solve this problem using B&B. Let $\mathcal{C}_r \subset \mathcal{N}_r$ denote a critical cutset of the nodes of the B&B tree used to solve (RO_r) . Then, $\bar{t}^r = \bar{t}^r$ for any refinement $\mathcal{X}_r$ of $\mathcal{X}_r$ for which for every $s \in \mathcal{S}_r$,

$$\bigcup_{n \in \mathcal{C}_r} \bar{Z}_{r,n,s} \subseteq Z_{r',s'}, \quad (1)$$

for some $s' \in \mathcal{S}_r$. That is, for such refinements $\mathcal{Z}_{r'}$ the objective function value does not improve.

Proof. Assume w.l.o.g. that $\mathcal{S}_r \subset \mathcal{S}_{r'}$ —that is, $\mathcal{S}_r \subseteq \mathcal{S}_{r'}$ and $\mathcal{S}_r \neq \mathcal{S}_{r'}$ —and that the split sets in $\mathcal{Z}_{r'}$ are indexed such that $\bar{Z}_{r,n,s} \subseteq Z_{r',s}$ for all $n \in \mathbb{O}_r$, $s \in \mathcal{S}_r$. Since $\mathcal{Z}_{r'}$ is a refinement of $\mathcal{Z}_r$, it follows immediately that $\bar{t}' \leq \bar{t}'$. It remains to show that also $\bar{t}' \geq \bar{t}'$ holds. We will do so by proving that $\bar{t}'$ is a lower bound for $(\text{RO}_{r'})$, the robust optimization problem after r' rounds of splitting, using the B&B tree of the r -th splitting round. Indeed, for each node $n \in \mathbb{O}_r$, we can consider $(\text{RO}_{r'})$ with the additional branching constraints from node $n \in \mathbb{O}_r$ (and without integrality restrictions):

$$\begin{aligned} \bar{t}'^{r,n} &:= \min_{t^{r,n}, x^{r,n}, y^{r,n,s}} t^{r,n} & (\text{RO}_{r',n}) \\ \text{s.t. } & t^{r,n} - c(z)^\top x^{r,n} - q(z)^\top y^{r,n,s} \geq 0 \\ & \forall z \in Z_{r',s} \quad \forall s \in \mathcal{S}_{r'} \\ & a_i(z)^\top x^{r,n} + w_i(z)^\top y^{r,n,s} \geq b_i \\ & \forall z \in Z_{r',s} \quad \forall i \in \mathcal{I}, \forall s \in \mathcal{S}_{r'} \\ & (d_j^{r,n})^\top x^{r,n} + \sum_{s \in \mathcal{S}_r} (e_j^{r,n,s})^\top y^{r,n,s} \geq \delta_j^{r,n} \\ & \forall j \in \mathcal{J}_{r,n} \quad (2) \\ & x^{r,n} \geq 0, y^{r,n,s} \geq 0 \quad \forall s \in \mathcal{S}_{r'}. \end{aligned}$$

Observe that the summation in (2) runs over $s \in \mathcal{S}_r$, which means that branching conditions are only added to decision variables that were also present in round r . Moreover, since $\mathbb{O}_r$ is a critical cutset satisfying (i) and (ii) in Definition 1, it follows that the optimal solution to the problem $(\text{RO}_{r'})$ is feasible for at least one node $n \in \mathbb{O}_r$, and thus the minimum objective value of $(\text{RO}_{r',n})$ over all nodes $n \in \mathbb{O}_r$ yields a lower bound for $\bar{t}'$:

$$\min_{n \in \mathbb{O}_r} \bar{t}'^{r,n} \leq \bar{t}'.$$

Next, we will use the dual problems of $(\text{RO}_{r,n})$ and $(\text{RO}_{r',n})$, and the fact that $\bar{t}'^{r,n} \geq \bar{t}'$ for all $n \in \mathbb{O}_r$, to prove that $\bar{t}' \leq \bar{t}'^{r,n}$ for every $n \in \mathbb{O}_r$, and thus

$$\bar{t}' \leq \min_{n \in \mathbb{O}_r} \bar{t}'^{r,n} \leq \bar{t}'. \quad (3)$$

After obtaining the robust counterpart $(\text{P-RC}_{r,n})$ of $(\text{RO}_{r,n})$, its dual is given by $(\text{D-RC}_{r,n})$ and by Proposition 1, strong LP duality holds between the two. Similarly, the dual of $(\text{RO}_{r',n})$ is equivalent to

$$\max_{\lambda_i^{r,n,s}, u_i^{r,n,s}, \mu_j^{r,n}} \sum_{s \in \mathcal{S}_{r'}} \sum_{i \in \mathcal{I}} \lambda_i^{r,n,s} b_i + \sum_{j \in \mathcal{J}_{r,n}} \mu_j^{r,n} \delta_j^{r,n} \quad (\text{D-RC}_{r',n})$$

$$\begin{aligned} \text{s.t. } & \sum_{s \in \mathcal{S}_{r'}} \lambda_0^{r,n,s} = 1 \\ & \sum_{s \in \mathcal{S}_{r'}} \left(\lambda_0^{r,n,s} \bar{c} + C u_0^{r,n,s} \right) - \sum_{i \in \mathcal{I}} \sum_{s \in \mathcal{S}_{r'}} \left(\lambda_i^{r,n,s} \bar{a}_i + A_i u_i^{r,n,s} \right) \\ & \quad - \sum_{j \in \mathcal{J}_{r,n}} \mu_j^{r,n} d_j^{r,n} \geq 0 \\ & \lambda_0^{r,n,s} \bar{q} + Q u_0^{r,n,s} - \sum_{i \in \mathcal{I}} \left(\lambda_i^{r,n,s} \bar{w}_i + W_i u_i^{r,n,s} \right) \\ & \quad - \sum_{j \in \mathcal{J}_{r,n}} \mu_j^{r,n} e_j^{r,n,s} \geq 0, \quad \forall s \in \mathcal{S}_r \\ & \lambda_0^{r,n,s} \bar{q} + Q u_0^{r,n,s} - \sum_{i \in \mathcal{I}} \left(\lambda_i^{r,n,s} \bar{w}_i + W_i u_i^{r,n,s} \right) \geq 0, \\ & \quad \forall s \in \mathcal{S}_{r'} \setminus \mathcal{S}_r \\ & p^{r',s} u_i^{r,n,s} \leq \lambda_i^{r,n,s} p^{r',s}, \quad \forall i \in \mathcal{I} \cup \{0\}, \quad \forall s \in \mathcal{S}_{r'} \quad (4) \\ & \lambda_i^{r,n,s} \geq 0, \mu_j^{r,n} \geq 0, \quad \forall i \in \mathcal{I} \cup \{0\}, \quad \forall j \in \mathcal{J}_{r,n}, \quad \forall s \in \mathcal{S}_{r'}. \end{aligned}$$

Observe that it is possible to select $u^{r,n,s} = 0$ and $\lambda^{r,n,s} = 0$ for all $s \in \mathcal{S}_{r'} \setminus \mathcal{S}_r$ to obtain the same dual as in $(\text{D-RC}_{r,n})$ except that $p^{r',s}$ and $p^{r',s}$ in the constraints in (4) refer to the split uncertainty sets in $\mathcal{Z}_{r'}$, whereas in $(\text{D-RC}_{r,n})$ they refer to the uncertainty sets in $\mathcal{Z}_r$. These constraints, however, can be written in a different form, since the uncertainty sets $Z_{r',s} = \{z \in \mathbb{R}^L : p^{r',s} z \leq p^{r',s}\}$ are bounded and thus $p^{r',s} z \leq 0 \Rightarrow z = 0$; see, for example, Schrijver (1986). Hence, if $\lambda_i^{r,n,s} = 0$, then $u_i^{r,n,s} = 0$, and if $\lambda_i^{r,n,s} > 0$, then the constraint reduces to

$$p^{r',s} \left(\frac{u_i^{r,n,s}}{\lambda_i^{r,n,s}} \right) \leq p^{r',s} \Leftrightarrow \frac{u_i^{r,n,s}}{\lambda_i^{r,n,s}} \in Z_{r',s}.$$

Using this alternative form, and since $\bigcup_{n \in \mathbb{O}_r} \bar{Z}_{r,n,s} \subseteq Z_{r',s}$ for all $s \in \mathcal{S}_r$, it is not hard to verify that the optimal dual solutions of $(\text{D-RC}_{r,n})$ can be used to construct a feasible solution to $(\text{D-RC}_{r',n})$ for every $i \in \mathcal{I} \cup \{0\}$ and $j \in \mathcal{J}_{r,n}$:

$$\begin{aligned} \lambda_i^{r,n,s} &:= \begin{cases} \bar{\lambda}_i^{r,n,s} & \text{if } s \in \mathcal{S}_r \text{ and } \bar{\lambda}_i^{r,n,s} > 0, \\ 0 & \text{otherwise,} \end{cases} \\ u_i^{r,n,s} &:= \begin{cases} \bar{u}_i^{r,n,s} & \text{if } s \in \mathcal{S}_r \text{ and } \bar{\lambda}_i^{r,n,s} > 0 \\ 0 & \text{otherwise,} \end{cases} \\ \mu_j^{r,n} &:= \bar{\mu}_j^{r,n}. \end{aligned}$$

The objective value of this dual solution is at least $\bar{t}'$ by definition of a critical cutset. Thus, for all $n \in \mathbb{O}_r$, we have by weak LP duality that $\bar{t}'^{r,n} \geq \bar{t}'$, and thus by (3) we conclude that $\bar{t}' \leq \bar{t}'$. $\square$

Theorem 1 shows how to detect critical scenarios to be split for mixed-integer adjustable RO problems in general. In Section 4 we will show that this critical scenario detection method outperforms existing problem-specific heuristic methods. First, however, we remark that Theorem 1 implies a simple optimality criterion for when to stop splitting the uncertainty set.

Corollary 1. Let $\mathbb{C}_r \subset \mathcal{N}_r$ denote a critical cutset of the nodes of the B&B tree used for solving (RO_r) , and suppose that

$$\left| \bigcup_{n \in \mathbb{C}_r} \bar{Z}_{r,n,s} \right| \leq 1, \quad \forall s \in \mathcal{S}_r.$$

Then, for any refinement Z_r' of Z_r , we have $\bar{f}' = \bar{f}$, and thus the objective value of the adjustable RO problem (ARO) equals $\bar{f}$. □

Remark 3. Because of the strong LP duality between problems $(P-RC_{r,n})$ and $(D-RC_{r,n})$, the critical scenarios can be obtained at no cost from the optimal dual multipliers of the LP problem if $(P-RC_{r,n})$ is feasible. In a similar way, they can be obtained from the dual infeasibility ray of problem $(P-RC_{r,n})$ if $(P-RC_{r,n})$ is infeasible and $(D-RC_{r,n})$ is unbounded. In this way, no additional optimization problems need to be solved to construct the set of critical scenarios.

4. Numerical Experiment—Route Planning

4.1. Problem Description

To illustrate the potential benefits of our method, we consider the route planning problem from Hanasusanto et al. (2015) and Postek and den Hertog (2016). This is a problem with uncertainty in the objective function to which the methodology of Postek and den Hertog (2016) and Bertsimas and Dunning (2016) cannot be straightforwardly applied.

The problem is a shortest path problem defined on a directed graph $G = (V, A)$ with nodes $V = \{1, \dots, N\}$, arcs $A \subseteq V \times V$, and uncertain weights $w_{ij}(z) \in \mathbb{R}_+$ for every arc $(i, j) \in A$. We assume that these arc weights are affine functions of the uncertain parameters $z \in Z$, where Z is a polyhedral uncertainty set. The goal is to determine the length of the worst-case shortest path from a start node $b \in V$ to an end node $e \in V$ with $b \neq e$. This shortest path is determined after we observe the arc weights $w_{ij}(z)$, but its worst-case length is determined before these arc weights are known. If the arc weights represent travel times, then this problem can be interpreted as a route planning problem in which we determine the maximum time required to travel from node b to e .

The corresponding mixed-integer adjustable RO problem is given by

$$\begin{aligned} \min_{t, y(z)} \quad & t \\ \text{s.t.} \quad & t - \sum_{(i,j) \in A} w_{ij}(z) y_{ij}(z) \geq 0, \quad \forall z \in Z \\ & \sum_{(j,l) \in A} y_{jl}(z) - \sum_{(i,j) \in A} y_{ij}(z) \geq \mathbb{I}(j = b) - \mathbb{I}(j = e), \\ & \quad \quad \quad \forall j \in V \\ & y_{ij}(z) \in \{0, 1\}, \quad \forall z \in Z, \forall (i, j) \in A. \end{aligned} \tag{RPP}$$

Here, the binary variables $y_{ij}(z)$ are equal to 1 if arc (i, j) is part of the shortest path from b to e , and $\mathbb{I}(\cdot)$ denotes the indicator function.

Since this problem has uncertainty in the objective function only, the methodology of Postek and den Hertog (2016) only generates a single critical scenario, giving no indication on how to split the uncertainty set. That is why they propose problem-specific heuristic splitting rules that can only be applied to this route planning problem. In our numerical experiment, we show that our general B&B-based critical scenario detection method outperforms these splitting rules.

4.2. Experimental Design

We generate 50 random graphs with N nodes, where the location of each node is uniformly sampled from $[0, 10]^2$. The nodes between which the Euclidean distance is largest are designated as start and end node. Moreover, the arc set A is obtained by removing the longest 70% of arcs from a complete directed graph, as in Hanasusanto et al. (2015) and Postek and den Hertog (2016).

We assume that the arc weights $w_{ij}(z)$ are defined as

$$w_{ij}(z) = (1 + z_{ij}/2) d_{ij},$$

where d_{ij} represents the Euclidean distance between nodes i and j , and z is contained in the polyhedral uncertainty set

$$Z = \left\{ z \in [0, 1]^{|A|} : \sum_{(i,j) \in A} z_{ij} \leq B \right\}.$$

Thus, the arc weight $w_{ij}(z)$ may be between 100% and 150% of the distance d_{ij} between the nodes. For the parameter B in the uncertainty set we consider $B = 2, 3, 4$.

In our numerical experiment, we compare the quality of the uncertainty set splits based on (i) the problem-specific method of Postek and den Hertog (2016)

and (ii) our new B&B-based critical scenario detection method. For both methods, we split the uncertainty sets $Z_{r,s}$ for those $s \in \mathcal{S}_r$ for which the first constraint in (RO_r) is active. That is, we only focus on those uncertainty subsets that determine the worst-case objective value after the r -th splitting round. Each such set is split into two subsets using the bisecant plane between the two critical scenarios that are furthest apart from each other. A bisecant plane between two points z and z' is the hyperplane going through the point $(z + z')/2$ with normal vector $z - z'$.

The idea behind the heuristic of Postek and den Hertog (2016) is to find an alternative critical scenario z , so that z and z_{LP} , obtained using the LP-relaxation, can be split. This alternative scenario z is the worst-case scenario corresponding to an alternative path y from b to e . To make sure that z differs substantially from z_{LP} , this path y cannot use more than $100\theta\%$ of the arcs in the optimal path $y(z_{LP})$ corresponding to z_{LP} . Here, $0 \leq \theta \leq 1$ is a parameter that we can select. For details of this ad hoc method, see Postek and den Hertog (2016). Our new general critical scenario detection method identifies critical scenarios as explained in Definition 3. In our numerical experiments, we use the critical cutset $\mathbb{C}_r$ with smallest cardinality.

Remark 4 (ex Post Correction). Since our route planning problem (RPP) only has uncertainty in the objective function, it is possible to apply an *ex post correction* to the worst-case objective value after each round of splitting. The idea, not recognized in Postek and den Hertog (2016), is that the routes $y^{r,s}$ corresponding to uncertainty sets $Z_{r,s}$, $s \in \mathcal{S}_r$, after r rounds of splitting are feasible for any $z \in Z$. By selecting the best route

among $y^{r,s}$, $s \in \mathcal{S}_r$, for every $z \in Z$, the worst-case objective value becomes

$$\underline{t}_r := \max_{z \in Z} \min_{s \in \mathcal{S}_r} \sum_{(i,j) \in A} w_{ij}(z)^\top y_{ij}^{r,s}.$$

This objective value $\underline{t}_r$ may be lower than $\bar{t}_r$ since $y^{r,s'}$ is not necessarily the best solution among $y^{r,s}$, $s \in \mathcal{S}_r$, for all $z \in Z_{r,s'}$. In our numerical experiment, we apply this ex post correction and show both values $\underline{t}_r$ and $\bar{t}_r$.

4.3. Results

The numerical experiments are carried out on an Intel Core i5-6500 3.2-GHz machine with 8 GB of RAM. To obtain the critical scenarios in our B&B method, we have implemented a B&B procedure using the CVX 2.1 modeling framework (Grant and Boyd 2014) within MATLAB R2018a (MathWorks 2018). Codes and data can be found in the online supplement to this paper. All LPs in the nodes of the B&B tree are solved using Gurobi 8.1 (Gurobi Optimization 2019). The critical scenarios are based directly on the optimal dual variables of node subproblems in the critical cutset $\mathbb{C}_r$ of the B&B tree. We cannot use Gurobi, or any other commercial MILP solver, to solve (RO_r) since the optimal dual variables of the node subproblems are not accessible in such solvers.

In Table 1 we present results for a representative parameter set $N = 10, 20, 30, 40$, $\theta = 0, 0.5, 0.9$ and $B = 3$. For each value of N , the worst-case objective value improvement of (RO_r) compared with the objective value of (RO_0) is given, both for our B&B scenario detection method and the problem-specific method of Postek and den Hertog (2016) with $\theta = 0, 0.5, 0.9$. We report the worst-case objective value improvement after a single splitting round—that is, when the

Note. In bold, result of the approach that performed best for a given N if its average outperformance was statistically significant at 0.95 confidence level.

Figure 3. Objective Function Improvement (%) of the B&B and the Problem-Specific Methods Relative to the Number of Subsets Over the Splitting Process (with the ex Post Correction), for $N = 30$, $B = 3$

uncertainty set is partitioned into two subsets and thus $|\mathcal{Z}_r| = 2$, and when $|\mathcal{Z}_r| = 10$.

We observed that the results are very similar for $B = 2, 3, 4$, both for $|\mathcal{Z}_r| = 2$ and $|\mathcal{Z}_r| = 10$. The performance of the problem-specific heuristic, however, depends strongly on the parameter θ , and is better for $\theta = 0$ than for $\theta = 0.5$ and $\theta = 0.9$. Moreover, the ex post correction of the worst-case objective value discussed in Remark 4 also has a substantial impact. In all cases, it leads to a major increase in objective value improvement. For example, for $N = 40$ and $B = 3$, the improvement of our B&B scenario detection method is 5.00% without and 11.27% with ex post correction.

Comparing the B&B scenario detection method with the problem-specific method of Postek and den Hertog (2016), using the ex post corrected results, the B&B method outperforms the problem-specific method. In fact, for all N , the worst-case objective value improvement of the B&B method is statistically significantly better than the problem-specific method for all values of θ . This result is confirmed in Figure 3, where we show the worst-case objective improvements of both methods as a function of $|\mathcal{Z}_r|$, the number of subsets in which Z is partitioned, for $N = 30$ and $B = 3$. Observe that the largest objective value improvements are from the initial splits of the uncertainty set. Moreover, the increase in the objective value improvement diminishes with the number of splits.

The last row of Table 1 shows the running times of both methods for $|\mathcal{Z}_r| = 10$. Our B&B scenario detection method is faster than the problem-specific method of Postek and den Hertog (2016) on the small problem instances with $N = 10$, but significantly slower on the larger problem instances with $N = 40$. The main reason why our B&B method is slower is that we have to use a self-implemented B&B procedure to solve (RO_r) . In contrast, the problem-specific method of Postek and den Hertog (2016) also requires solving a MILP to obtain an alternative scenario z ; however, this MILP can be solved using Gurobi since no dual information of node subproblems is required.

We expect that with a faster B&B procedure for our B&B scenario detection method, the running times of both methods will be similar.

5. Summary

In this paper, we have considered piecewise constant decision rules for mixed-integer adjustable robust optimization (RO) by adaptively partitioning the uncertainty set, as proposed by Postek and den Hertog (2016) and Bertsimas and Dunning (2016). In this approach, the uncertainty set is iteratively partitioned into smaller subsets in such a way that so-called critical scenarios are located in separate subsets. An open issue in this context has been how to detect these critical scenarios in problems involving integer decision variables. That is why we have provided a general-purpose critical scenario detection method for such problems that is based on extracting the information hidden in the B&B tree used to solve the corresponding static mixed-integer RO problem. In particular, the critical scenarios are directly derived from the optimal dual vectors in the nodes of the B&B tree, at no extra computational cost. Using numerical experiments on a route planning problem, we have shown that our general-purpose method outperforms the problem-specific heuristic method of Postek and den Hertog (2016).
