Availability of CYP2D6 genotyping results in general practitioner and community pharmacy medical records

Aim: To investigate the availability of CYP450–2D6 (CYP2D6) genotyping results in general practitioner (GP) and/or community pharmacy records, and the influence thereof on psychotropic CYP2D6 substrate dosing. 

Materials & methods: Primary outcome was the percentage of patients genotyped for CYP2D6 with their genotype/phenotype registered in GP and/or pharmacy records. Secondary outcome was the number of defined daily doses of psychotropic CYP2D6 substrates prescribed after genotyping. Results: For 216 out of 1307 eligible patients, medication overviews could be obtained. Genotyping results were available at GPs for 3.1% and at pharmacies for 5.9%. The average psychotropic CYP2D6 substrate dose was not different between any non-extensive metabolizer group and extensive metabolizer group (all p ≥ 0.486). Conclusion: Valuable information for individualizing psychiatric pharmacotherapy is lost on a large scale.

First draft submitted: 3 March 2017; Accepted for publication: 5 April 2017; Published online: 8 June 2017

Keywords: clinical practice • communication • CYP450-2D6 • gene polymorphisms • medication safety • personalized medicine • psychiatry

CYP450–2D6 (CYP2D6) genotyping is probably the most widely accepted application of genotyping in psychiatric practice [1,2]. Approximately 5–10% of the Caucasian population can be classified as poor metabolizer (PM) by lacking CYP2D6 activity and 1–10% as ultrarapid metabolizer (UM) by gene duplication resulting in high enzyme activity. Furthermore, 30–35% of Caucasians are classified as intermediate metabolizer (IM) [3]. IMs have a metabolic capacity in between a PM and an extensive metabolizer (EM) with two active alleles [3]. A previous study has shown that 52% of psychiatric patients use at least one drug that is metabolized by CYP2D6 [4]. Out of the drugs metabolized by CYP2D6, 62% were classified as an antidepressant or antipsychotic [4]. These figures implicate that a substantial proportion of psychiatric patients are at risk of unsatisfactory response to psychotropic drugs due to polymorphisms in CYP2D6. The resulting number of patients needed to genotype (to find one additional psychiatric patient with compromised CYP2D6 metabolism [PM, IM and UM] treated with at least one drug metabolized by CYP2D6) is four [4].

In The Netherlands, recommendations are available for the choice of drug and dose based on the CYP2D6 phenotype, written by the Pharmacogenetics’ Working Group of the Royal Dutch Association for the Advancement of Pharmacy (WINAp/KNMP) guidelines [5,6]. The recommendations are incorporated in the Dutch computerized medication surveillance systems for physicians, and as such reach general practitioners (GPs), psychiatrists and pharmacists. These recommendations include guidelines for the application of CYP2D6 genotyping for appropriate drugs and potentially are a major step...
forward in the implementation of pharmacogenetic testing in daily clinical practice. However, in order to optimize the use of genotyping results, an important precondition is the adequate documentation of the CYP2D6 genotyping results in the medical records of the patient and communication to all healthcare providers involved with the individual patient.

The genetic laboratory of the Wilhelmina Hospital in Assen is one of the centers in The Netherlands that offer genotyping services. This laboratory performs about 350 CYP2D6 genotyping per year, predominantly ordered by physicians in mental healthcare institutions. Recent research of our group showed that there are clinically relevant shortcomings in the availability of the actual medication use in the medical records of psychiatric patients [7]. Given the potential lifetime benefits of a CYP2D6 genotyping and the absence of previous literature, we decided to quantify – for the first time – how genotyping results are communicated to other healthcare providers like the GP and/or community pharmacies, who have a central role in the delivery of care in The Netherlands.

Aim of the study
The primary objective of this study is to quantify the availability of CYP2D6 genotyping results in the medical records of the GP and/or community pharmacy. The secondary objective is to determine whether registration of the CYP2D6 genotyping result in the medical records influences the dosing of psychotropic drugs metabolized by CYP2D6 as suggested in the Dutch/International guidelines.

Material & methods
Design & setting
We cross-sectionally assessed the percentage of patients genotyped for CYP2D6 for whom the genotyping result was available in the medical record of their GP and/or community pharmacy. The extent to which the registration of the CYP2D6 genotyping result in the medical records influenced the dosing of psychotropic drugs metabolized by CYP2D6 was examined in a retrospective survey.

CYP2D6 genotypings were performed by the genetic laboratory of the hospital pharmacy of the Wilhelmina Hospital Assen (WHA), The Netherlands. The hospital pharmacy delivers pharmaceutical care to – among others – a large secondary mental healthcare institution. The hospital pharmacy is specialized in psychopharmacology and in the implementation of pharmacogenetics in patients with psychiatric disorders [8–10]. The genetic laboratory of the WHA is one of a few that perform pharmacogenetic tests. In The Netherlands, physicians and nursing specialists from any (mental) healthcare institution can order pharmacogenetic tests, including CYP2D6 from the WHA genetic laboratory. The CYP2D6 phenotype is determined on the basis of genotyping of CYP2D6 *3, *4, *5, *6, *10, *17 and *41, performed as described previously [11]. Approximately 90% of all CYP2D6 genotyping requests are ordered by psychiatrists treating patients in mental healthcare institutions, either directly or through a laboratory. Genotyping results, including the genotype and phenotype, are communicated on paper with the healthcare provider that requested the test. By Dutch law, the laboratory is not allowed to transfer this information to the medical records of the requestor or any other healthcare provider.

Study population
Patients were eligible if they were 18 years or older, and their CYP2D6 genotype was determined by genetic laboratory of the WHA between 1 February 2010 and 1 May 2015. The starting date was chosen 1 February 2010 because therapeutic recommendations based on the CYP2D6 phenotype were available for all psychotropic drugs metabolized by CYP2D6 from that date onward. Patients genotyped for CYP2D6 solely for (genetic) research purposes were excluded. Patients with both the IM phenotype and duplications in the CYP2D6 gene were also excluded, because their metabolic capacity cannot be predicted accurately.

As mentioned before, approximately 90% of all CYP2D6 genotyping requests come from psychiatrists working in mental healthcare institutions. With these requests, the names of the GP and pharmacy are not regularly provided. In order to trace the GP and community pharmacy for genotyped patients, we screened two databases (the WHA medical records and the National First-line Healthcare shared database). Furthermore, we asked the retrieved healthcare providers for additional names of GPs and community pharmacies of their patients.

Patients were included in the study if they were genotyped by the laboratory of the WHA and an actual medication record was available from their GP and/or their community pharmacy. If, in addition, the medication history was available at the community pharmacy only, patients were included for analysis of the secondary objective. We were logistically unable to collect information on the race or ethnicity of the patients, which appears irrelevant for our research aims.

The independent medical ethics committee in Leeuwarden, The Netherlands (iTPO Leeuwarden), waived formal review of the study protocol since participants were not subject to procedures, nor were they required to follow any rules of behavior. As this study was a
Critical evaluation of the process around genotyping at the genetic laboratory of the WHA, no informed consent from patients was needed by the Dutch law, as confirmed in writing by the legal expert of the rTPO Leeuwarden.

Primary outcome
The primary outcome was the percentage of patients genotyped for CYP2D6 for whom genotyping results were available at their GP, community pharmacy, GP or community pharmacy, and GP and community pharmacy. Availability of the genotyping results in the medical health records at these healthcare providers was assessed by requesting an actual medication overview (which, by definition, includes contraindications such as the CYP2D6 genotyping result) and checking if the CYP2D6 genotype or phenotype was present on it. We hypothesized that genotyping results indicating a non-EM phenotype would be communicated to other healthcare providers more often than genotyping results indicating an EM phenotype. Therefore, we also compared the availability of test results between patients with EM and non-EM phenotypes.

Secondary outcome
The secondary outcome was the average number of defined daily doses (DDDs) per patient year of use of psychotropic drugs metabolized by CYP2D6 by each patient in the period between the date of the genotyping and 1 May 2015 (or date of death, whichever occurred first; the observation period; DDDs per patient year). A CYP2D6 substrate psychotropic drug was defined as any oral, rectal or parenteral drug approved by the Dutch Medicines Evaluation Board or the European Medicines’ Evaluation Authority with the anatomical therapeutic chemical (ATC) code starting with N05 or N06, which is metabolized by CYP2D6, and as such is mentioned in the WINAp/KNMP guidelines with the necessity to perform a therapeutic intervention in case of an aberrant CYP2D6 phenotype (e.g., choose another drug or adjust dose). These criteria apply to 13 drugs: amitriptyline, aripiprazole, atomoxetine, clomipramine, doxepin, haloperidol, imipramine, nortriptyline, paroxetine, pimozide, risperidone, venlafaxine and zuclopenthixol. We investigated the difference in DDDs per patient year between groups of patients for whom the genotyping result was, or was not, registered in the medical records at the GP and/or community pharmacy. In addition, we investigated data for potential effect modification by the CYP2D6 phenotype, using the ‘availability of the genotyping result*phenotype’ interaction term.

Statistical analysis
We performed descriptive and statistical analyses using Excel 2013 (Microsoft, WA, USA) and IBM SPSS (version 24 for Windows; IBM Corp., NY, USA). For comparison of differences in categorical variables, we used χ² tests or Fisher’s exact tests as appropriate, and for comparison of differences in continuous variables we used t-tests or linear regression techniques in case multivariate analysis was appropriate. We report medians (range) when distributions are not distributed normally. In all analyses, differences were considered statistically significant for the two-tailed test if p < 0.05.

In order to investigate the association between the CYP2D6 phenotype (categorized as EM and non-EM phenotypes) and the availability of the CYP2D6 genotyping results in the medical records at the GP and community pharmacy, we used logistic regression analysis. As genotyping information may be lost over time - for example when a patient switches from GP and/or community pharmacy - , the chance that a genotyping result is still adequately registered in the medical records shortly after the genotyping is higher than a few years later. In order to avoid inflation of our regression analysis results by this bias, we wanted to correct for the time between the date of the genotyping and the date of extraction of the actual medication overview in these models.

We investigated the association between the availability of the genotyping results in the medical records at the GP and/or community pharmacy and the number of DDDs per patient year of use across all prescribed psychotropic CYP2D6 substrates under study, by using a linear regression model. In order to prevent bias by higher DDDs with shorter duration of follow-up because of less time for trial and error, in case the WINAp/KNMP guidelines are not followed, we corrected for the length of the observation period. In addition, we investigated potential effect modification by the CYP2D6 phenotype using the ‘availability of the genotyping result*phenotype’ interaction term in this model.

Results
Study population
Figure 1 shows the flow chart for patient eligibility and inclusion. Between 1 February 2010 and 1 May 2015, the genetic laboratory of the WHA had performed 1388 CYP2D6 genotyping procedures, including 20 duplicate tests, for 1307 unique, eligible patients. Of all eligible patients, we were able to retrieve contact details and requested data from a GP for 279 patients and from a community pharmacy for 244 patients. Included and excluded patients were not different regarding age (p = 0.881), phenotype (p = 0.693) or year of genotyping (p = 0.596). We were unable to test directly whether
they differed in their requesting (mental) healthcare institution as more than half of all genotyping (51.6%) were requested indirectly through a laboratory, and we could not logistically verify the original requesting institutions. For 216 unique patients, we received up-to-date medication overviews from the GP and/or community pharmacy. The most important reasons for not including otherwise eligible patients were unavailability of or incorrect name of the GP and/or community pharmacy or the healthcare provider refusing to provide data for privacy reasons (despite approval of the study and waiver of informed consent).

Characteristics of the included patients are summarized in Table 1. Directly addressed genotyping requests (35/216, 16.2%) came from 13 different (mental) healthcare institutions throughout The Netherlands. For 166 patients we could retrieve the medication history from the community pharmacy for the period from the genotyping to 1 May 2015, for answering our secondary research question.
Primary outcome
Genotyping results were registered in the medical records at the GP for six of 191 patients (3.1%), and at the community pharmacy for 11 of 187 (5.9%; Table 2). In six of 162 patients (3.7%), the genotyping result was available at both the GP and the community pharmacy. Because none of the test results indicating EM were available at a GP or community pharmacy and the number of subjects with transferred phenotype (PM, IM and UM) results were low, we were restricted to \( \chi^2 \) tests instead of logistic regression analysis. Therefore, we could not correct for potential bias by increasing time between the date of the genotyping and the date of extraction of the actual medication overview. Non-EM phenotypes (PM, IM and UM taken together) were communicated more often to GPs and to community pharmacies than EM phenotypes (both \( p < 0.010 \); Table 2). Of note, only IM and PM phenotypes were communicated, while none of the EM and UM phenotypes were available at GPs or community pharmacies.

Secondary outcome
The phenotypic distribution of the patients for whom we could retrieve the medication history (\( n = 166 \)) was similar to the total sample (\( n = 216 \)). Half of these patients (87/166; 52.4%) had used no psychotropic CYP2D6 substrates for which an intervention is advised in the WINAp/KNMP guidelines during the observation period. Risperidone was used by 24 patients (14.5%), nortriptyline by 21 patients (12.7%), venlafaxine by 18 patients (10.8%) and both aripiprazole and haloperidol were used by 12 patients (7.2%). Amitriptyline, atomoxetine, clomipramine, doxepin, imipramine, paroxetine, pimozide and zuclopenthixol were used by eight patients or fewer (\( \leq 4.8\% \)).

The median duration of follow-up was 862 days (range: 3–1884 days). Patients for whom the test results were still available at the GP and/or community pharmacy had been prescribed on average 133.27 DDDs of psychotropic CYP2D6 substrates per patient year less than patients for whom the result was not available. This difference was corrected for the duration of follow-up and was not statistically significant (\( p = 0.341 \)). Since none of the EM and UM phenotypes were available at GPs or community pharmacies, we could not investigate potential effect modification by the CYP2D6 phenotype using the ‘availability of the genotyping result’phenotype’ interaction term, due to collinearity issues. We therefore used a linear regression model to investigate whether the psychotropic CYP2D6 substrate dose (in DDDs per patient year) was different between any of the non-EM phenotype groups compared with the EM phenotype, still correcting for the duration of follow-up, but irrespective of the availability in the medical records at the GP and/or community pharmacy. The average psychotropic CYP2D6 substrate dose was 183.8 corrected DDDs per patient year (95% CI: 57.4–310.3). This dose decreased with increasing CYP2D6 metabolic activity according to phenotype with 253.3 (95% CI: -97.9 to 604.5) DDDs per patient year for PMs and 111.7 (95% CI: -443.0 to 666.4) DDDs per patient year for UMs. However, there was no linear relationship (\( p = 0.514 \)) and the differences were not significant between any of the non-EM phenotype groups compared with the EM phenotype group (all three values of \( p \geq 0.486 \)).

Discussion
To take full advantage of the lifelong benefits of genotyping results in psychiatric patients, it is critical to communicate genotyping results to other healthcare providers. To our knowledge, this is the first study that investigated the extent to which genotyping results were communicated with other healthcare providers. We found that the transfer of CYP2D6 genotyping results from the requesting physician to GPs and community pharmacies is poor. CYP2D6 genotyping results were adequately registered in the medical records for only 3.1 and 5.9% of patients genotyped for CYP2D6 at the GP and community pharmacy, respectively. All cases of

CYP2D6: CYP450–2D6.
registered test results concerned CYP2D6 IM or PM phenotypes, which were present in 35.6 and 8.8% of the study population, respectively. This is indicative of a large loss of important information. We could not detect any significant differences between the phenotype groups in dosing of psychotropic CYP2D6 substrate drugs, suggesting that no adjustment of pharmacotherapy had been performed after genotyping, despite recommendations thereof in the W1NAp/KNMP guidelines.

Strengths & limitations
The strength of this study is the large population obtained from different (mental) healthcare institutions nationwide. We believe that our results can therefore be extrapolated to the Netherlands and, given our high standard of care, presumably also to other countries with similar healthcare systems. However, a few limitations apply. First, many eligible patients could not be included, and for some included patients, there were missing data for one of both healthcare providers. The main reason for these exclusions and missing data was the absent, incorrect or not up-to-date name of the GP and/or community pharmacy. However, we were able to show that included and excluded patients were not different regarding age (p = 0.881), phenotype (p = 0.693) or year of genotyping (p = 0.596). In addition, any potential selection bias seems unlikely to be based on the institution which requested the genotyping, as the communication of CYP2D6 genotyping results did not differ between patients for whom the genotyping was requested directly by their institution (p = 0.189) or between those patients and patients for whom the laboratory requested the genotyping (p = 0.417). We were able to include patients from at least 13 different (mental) healthcare institutions. Nevertheless, any bias because of missing data would probably result in an underestimation of the percentage of available CYP2D6 genotyping results in our study because the records for patients without a name of a GP and/or community pharmacy may be poorly filled and updated for CYP2D6 genotyping results as well. Still, exclusion of subjects reduced the power of our analysis and may affect the robustness of the findings. In addition, the low numbers of patients in specifically the PM and UM phenotype groups and the fact that none of the UM and EM patients had a registered genotyping result at their GP and/or community pharmacy, hampered our original plans for analyses. Nevertheless, in our alternative analysis without correction for time since the genotyping, we showed significant differences in reporting the CYP2D6 phenotype. Furthermore, we found no differences between the dosages of psychotropic CYP2D6 substrate drugs for the various phenotypes (irrespective of the registration of the genotyping results at the GP and/or pharmacy). Concomitant use of CYP2D6 inhibiting drugs may be a partial explanation for a lack of difference in dosing of psychotropic CYP2D6 substrate drugs. In a posthoc analysis, after we excluded all non-PM patients who used psychotropic CYP2D6 substrate drugs and at least one strong non-paroxetine CYP2D6 inhibitor (according to the Dutch Health Base Foundation classification ≥++ [12]: bupropion, cinacalcet, fluoxetine, kinidine, mirabegron, ritonavir and terbinafine; n = 5) concomitantly, we still found no differences in psychotropic CYP2D6 substrate dosing between the phenotype groups (p ≥ 0.454) or a linear association (p = 0.479). We excluded paroxetine because this is both a CYP2D6 substrate and an inhibitor, and this is already taken into account in the phenotype-based dosing recommendations. Therapeutic drug monitoring is another way to adjust the CYP2D6 substrate drug dose to the CYP2D6 metabolic capacity without the knowledge of the CYP2D6 genotype or phenotype. In another posthoc analysis, after we excluded drugs for which regular therapeutic drug monitoring is advised (amitriptyline, clomipramine, imipramine and nortriptyline), we again found no differences between the dosages of psychotropic CYP2D6 substrate drugs for the various phenotypes (p > 0.888) or a linear association (p = 0.866). So we feel quite convinced that in this sample, no CYP2D6 phenotype-based adjustment of pharmacotherapy has
been performed in regular clinical practice. Because of
the abovementioned limitation, we cannot adequately
evaluate the influence of the correct or absent reg-
istration of the genotyping result at the GP and/or
pharmacist on dosing of psychotropic CYP2D6 sub-
strate drugs, nor assess the extent to which specific
recommendations in the WINAp/KNMP guidelines
in clinical practice have been followed.

Second, our study concerned prescribed dosages of
psychotropic CYP2D6 substrate drugs and expect-
ations about effects of nonadjusted doses following
the WINAp/KNMP guidelines, while we were unable
to collect data about more direct results of different
CYP2D6 phenotypes: adverse effects or treatment
failures.

Finally, we could not distinguish between reasons
for the poor availability of genotyping results in the
medical records at GPs and community pharmacies.
One reason could be noncommunication of the test
results by the physician who ordered the genotyping;
another reason could be that the GP/pharmacist did
not enter the communicated test results in the patient’s
electronic medical records as a contraindication that
is taken into account by the medication surveillance
system.

Registration of CYP2D6 genotyping results in
perspective of previous literature
To the best of our knowledge, we are the first to
investigate the availability of CYP2D6 genotyping
results in the medical records at the GP and the com-

munity pharmacy, who are – at least in The Neth-

erlands – the ultimate first-line, and often lifelong,
healthcare providers for every patient. One previous
study described the extent of registration and transla-
tion of CYP2D6 and CYP2C19 genotyping results in
daily clinical routine based on medical records within
a psychiatric center [13]. In 53 out of 101 cases, their
PM or/and UM status for CYP2D6 and/or CYP2C19
was mentioned in the medical record; in 33% of the
cases, the deviant genotyping result was mentioned in
the discharge letter; and in 4% of the cases, it was
noted in the observations space [13]. Compared with
this study within a center, we found even worse avail-
ability of genotyping results in the medical records of
first-line healthcare providers. The lack of communi-
cation regarding genotyping results prevents health-
care providers to use the opportunities of personalized
healthcare at a large scale and ignores a very favor-
able number needed to genotype [4]. This should be
improved in order to fully utilize the information from
the genotyping procedure, to optimize personal-
ized medicine and to prevent duplicate tests (as we
found for 19 patients).

Implications for clinical practice
In a recent meta-analysis of three prospective clin-
ical trials, integrated pharmacogenetic testing guiding
psychiatric treatment has been shown to increase the
odds of a clinical response to antidepressant treatment
2.3-fold, with a number needed to treat of six for one
clinical response compared with treatment as usual [14].
Although this suggests a large potential for CYP2D6
genotyping for increasing treatment effectiveness by
individualizing antidepressant treatment, we point to
the fact that the transfer of such genotyping results to
other relevant healthcare professionals can be improved
substantially. Good communication and storage is a
crucial precondition in order to cost-effectively imple-
ment CYP2D6 genotyping in daily clinical practice.
This appears particularly important for (psychiatric)
patients treated by different healthcare providers and
in patients admitted to different institutions on a reg-
ular basis. Psychiatric patients are vulnerable and at risk
for the lack of communication between healthcare pro-
viders, as found in this study. Furthermore, CYP2D6
genotyping results can also be applied to somatic drugs
like metoprolol and tramadol as prescribed by the GP.
The lack of communication of the CYP2D6 genotyping
result to the GP puts the patient at risk, unnecessarily,
for adverse events for somatic drugs as well.

Several opportunities to improve communication
of genotyping results exist. First, the best solution
probably is a direct, digital communication of the test
results from the laboratory to the electronic medical
records of the GP and community pharmacy, in addi-
tion to the report sent to the requestor. However, in
The Netherlands, privacy legislation has so far ham-
pered the implementation of such a direct communi-
cation. Second, it is important to clarify and subse-
tively decrease barriers for communication of genotyping
results to, and registration by, GPs and pharmacists.
Third, improvement of knowledge about application
of the results will reinforce the way this information is
appreciated and used. Previous research indeed showed
the necessity for more effective physician education on
the clinical value, the importance of communicating
the genotyping results, the interpretation and the appli-
cation of the results with respect to drug choices and
dosing strategies [15]. Fourth, the genotyping and result
as well as the implications for dosing of pharmaco-
therapy should be discussed with the patient [16].
Patients appear to be interested in the background and
consequences of the genotyping, and want to receive
the results [17–20], which may even improve medication
adherence [21]. Still, about a third of patients may wish
to withhold these results from their physicians because
they feel that their doctors are too busy, not interested
or incompetent [17]. To our opinion, informing patients
about their test results cannot, therefore, replace communication of patient information between health-care providers. In addition, a genetic passport could be handed out by every genetic laboratory that lists a person’s pharmacogenetic profile [22]. This passport might be useful to transfer the genotyping results to first-line healthcare providers and avoids privacy legislation problems. Also, it may contain machine-readable data for use in clinical decision support systems used by GPs and pharmacists [22].

Conclusion
In conclusion, we demonstrate that communication of genotyping results to other healthcare professionals like GPs and pharmacies needs improvement, in order to utilize the clinical benefits of CYP2D6 (and other) genotypings. This will provide valuable information for individualizing pharmacotherapy and prevents the large-scale loss of information about (psychiatric) patients.

The authors state that they have obtained appropriate institutional review board approval or have followed the principles outlined in the Declaration of Helsinki for all human or animal experimental investigations.

Summary points
- Although highly relevant for clinical decisions on dosing, CYP450–2D6 (CYP2D6) genotyping results are poorly transferred from requesting (mental) healthcare institutions to general practitioners (GPs) and community pharmacy medical records: <10% of the genotyping results were adequately registered.
- Nonextensive metabolizer phenotypes (poor metabolizer, intermediate metabolizer and ultrarapid metabolizer taken together) were communicated more often to GPs and to pharmacies than extensive metabolizer phenotypes (both p < 0.010).
- We could not detect any significant differences between CYP2D6 phenotype groups in dosing of psychotropic CYP2D6 substrates, indicating that no phenotype-based adjustments of pharmacotherapy had been performed, despite recommendations in Dutch/International guidelines.
- Due to missing data, many eligible patients could not be included, which hampered our primary and secondary objectives.
- This study used prescription records of GPs and community pharmacies. Therefore, we were unable to investigate whether the availability of genotyping results was associated with adverse events or treatment failures.
- Communication of genotyping results to other healthcare professionals like GPs and pharmacies needs to be improved, in order to prevent valuable information for individualizing pharmacotherapy of psychiatric patients from being lost on a large scale.
- Probably the best way to improve communication of genotyping results is a direct, digital communication of the test results from the laboratory to the electronic medical records of the GP and pharmacy in addition to the report sent to the requestor. However, in The Netherlands, privacy legislation has so far hampered the implementation of such a direct communication.
- More effective physician education on the clinical value, the importance of communicating the genotyping results, the interpretation and the application of the results with respect to drug choices and dosing strategies may result in optimized utilization of the potential lifetime clinical benefits of CYP2D6 (and other) genotypings.
