Supporting Information

ABSTRACT: The coupling of substituted carbazole compounds through carbon-carbon bond formation upon one-electron oxidation is shown to be a highly versatile approach to the formation of redox polymer films. Although the polymerization of single carbazole units has been proposed earlier, we show that by tethering pairs of carbazoles double sequential dimerization allows for facile formation of redox polymer films with fine control over film thickness. We show that the design of the monomers and in particular the bridging units is key to polymer formation, with the diaminobenzene motif proving advantageous, in terms of the matching to the redox potentials of the monomer and polymer film and thereby avoiding limitations in film thickness (autoinsulation), but introduces unacceptable instability due to the intrinsic redox activity of this moiety. The use of a diimide protecting group both avoids complications due to p-diamino-benzene redox chemistry and provides for a redox polymer in which the photoluminescence of the bis-carbazole moiety can be switched reversibly (on/off) with redox control. The monomer design approach is versatile enabling facile incorporation of additional functional units, such as naphthalene. Here we show that a multicomponent carbazole/naphthalene containing monomer (APCNDI) can form redox polymer films showing both p- and n-conductivity under ambient conditions and allows access to five distinct redox states, and a complex electrochromic response covering the whole of the UV/vis–NIR spectral region. The highly effective quenching of the photoluminescence of both components in poly-APCNDI enables detailed characterization of the redox polymer films. The poly-APCNDI films show extensive charge trapping, which can be read out spectroscopically in the case of films and is characterized as kinetic rather than chemical in origin on the basis of UV/vis–NIR absorption and resonance Raman spectroscopic analyses. The strong resonantly enhanced Raman scattering for the various oxidized and reduced states of APCNDI enables nondestructive “read-out” of the state of the polymer, including that in which charges are trapped kinetically at the surface, making poly-APCNDI highly suitable for application as a component in organic nonvolatile memory devices.

INTRODUCTION

Smart (stimuli responsive) surfaces1 are attracting increasing attention,2−4 not least in the field of molecular electronics,5 due to the opportunities presented by redox switching in rapid localized control of physical and optical properties. Electrochromism, the inducing of reversible color changes by application of a voltage, was first observed in inorganic semiconductors.6 The later discovery of organic conducting polymers7 enabled facile processing and application to foldable devices. D–A–D (donor–acceptor–donor) oligoimides in particular have seen application already in high-performance nonvolatile memory devices,8−16 logic gates,17 and nonlinear optical materials.16,19 Intra- and intermolecular interactions in such multicomponent systems often alter the functionality of their individual components,20,21 which can provide opportunities in their application. Carbazole and its derivatives have been widely studied for their various physical and electronic properties, the most studied of which, poly(N-vinylcarbazole), was the first nitrogen heterocycle containing polymer to show hole transport properties.22 The discovery of the optical and electrical properties of carbazole containing polymers and oligomers has stimulated their application in areas as diverse as organic light emitting diodes (OLEDs) and organic-thin film transistors,23−25 organic solar cells,26−28 and sensors.29

Carbazole is often modified with a moiety to allow for incorporation in a polymer, e.g., with vinyl groups30,31 or through Suzuki coupling,32 since although the ability of N-substituted carbazoles to undergo polymerization has been proposed, Karon and Lapkowski concluded, in their recent review, that oxidation of N-substituted carbazoles leads mainly to dimers as a consequence of charge delocalization in the 3′−3′ dimer.33 Indeed, Siove and co-workers showed that a monomer in which two carbazole units are tethered by an N-substituted...
alkyl spacer merely leads to sequential dimerization upon chemical oxidation to form a polymer that could be spin-cast on electrodes. The C−C coupling para to the nitrogen upon (electro)oxidation via a 4 electron ECCE process is analogous to the dimerization of indoline derivatives and N,N-dialkyl substituted anilines, which occur readily. Moreover, direct coupling of two of such moieties covalently via the amine group results in chain-growth elongation of the bisindoline scaffold (Scheme 1) with each unit coupling to another molecule.

Koyuncu et al. reported a carbazole coupled to either perylene or naphthalimide to form energy donor/acceptor (D−A) systems, which can be immobilized by electrochemical coupling of the carbazole units. The films formed show moderate quenching of the fluorescence of both donor and acceptor in the dyads but almost complete quenching of photoluminescence in the films formed electrochemically. The use of only a single carbazole unit in this system, however, requires that each carbazole unit couples to two others in order to form a polymer backbone with pendant naphtal- and perylene-imide units. However, the steric overcrowding expected in the system reported by Koyuncu et al., the stability of the initially formed bis-carbazole dication (which is present at the potentials required for oxidation of monomer), and the poor mechanical stability of the films formed, indicate that dimerization rather than polymerization occurred, with insolubility being the primary driving force for immobilization on the electrodes used. The choice of spacer unit between the carbazole and perylene/naphtalimide (Scheme 1) has a pronounced effect on the efficiency of carbazole−carbazole coupling and the final structure of the films formed.

The spacer unit, in such systems, plays an important role in determining the overall function of the systems. Earlier studies on compounds in which a functional unit, such as a dithienylethene photochromic switch, was tethered to a pair of electrodimerizable/polymerizable units showed that the introduction of a phenyl spacer aids the polymerization process and improves the retention of the functionality of the photoswitchable moiety. Koyuncu et al. took a similar approach in which carbazole units are attached directly at their 3-position to both ends of a naphthalene diimide, enabling polymerization through sequential dimerization.

1,4,5,8-Naphtalene diimides (NDIs) are chemically robust chromophores which have seen widespread application over the last decades in supramolecular systems such as rotaxanes.
catenanes, nanotubes, ion channels, foldamers, and synthetic photosystems. Their tendency to self-organize both at the solid state and in solution due to their planarity and to engage in ππ stacking has made them appealing to supramolecular chemistry as they can form or be incorporated readily within supramolecular assemblies. Furthermore, the electronic properties of NDI have found application in sensing and in multicomponent systems in which energy and electron transfer processes are utilized. For example, Takenaka et al. have employed an NDI bearing redox-active ferrocenyl moieties to discriminate between double stranded DNA and single stranded DNA electrochemically. The radical monoanionic form of NDI is readily accessible by chemical and electrochemical reduction, and its electron deficiency in its neutral state favors interaction with electron rich species and anions as highlighted elegantly by Mattie et al. in their study of charge transfer (anion-π interactions) and transport between substituted NDI monomers and nanorods with a variety of anions. More recently, Saha et al. reported light-gated electron transfer from anions to aryl substituted NDL.

The wider range of applications that can be realized makes the combination of carbazole and NDI in an electrochromic polymer film highly appealing. Several approaches toward this goal have been reported to date, making use of various carbazole structures and naphthalene derivatives (Figure 1). Kozych and co-workers observed quenching of the emission at 700 nm in a D–A carbazole–naphthalene imide polymer obtained through chemical coupling. A drawback of the latter approach is the synthetic effort of chemical coupling, as well as the risk of presence of residual palladium, which limits the range of applications. Lav et al. utilized the propensity of tethered carbazoles to dimerize, forming numerous cross-links through sequential electrodimerization in an oligomer containing carbazole side chains. The key challenge in forming robust redox polymers based on the combination of NDI and carbazole is to achieve polymerization rather than dimerization and to avoid other electrochemically induced reactions.

Here, we report the synthesis and characterization of amino-phenyl carbazole cyclohexane diimide (APCCDI), Figure 2, and its oxidative electropolymerization on a range of electrode materials under ambient conditions, i.e., without need for strong Lewis acids or inert conditions. The optical and electrochemical properties of the monomer and redox-active polymer films are characterized by UV/vis, FTIR and emission spectroscopy, and cyclic voltammetry.

In addition, two carbazole compounds were prepared for modeling of the oxidative coupling and the impact of the functional groups present in the multicomponent systems on electrochemical stability (Figure 3 and Scheme 2). We show that while the diimide unit performs well under electrochemical conditions, the use of a simpler N-aryl amide linkage D1 shows instability due to the quinoidal character of the oxidized p-diamino linker, with decomposition competing with carbazole-carbazole coupling.

Model compounds such as the benzoate based D2, however, showed the expected spectroscopic properties of the carbazole dimers after oxidative electrolysis, with a slight red-shift in both the UV/vis absorption and fluorescence spectra. The model monomer (I1) and dimer (I2) of APCCDI, with a single instead of double diimide, provide insight into its properties in the monomeric and polymeric form.

The electrochemical performance of the phenyl carbazole unit, linked through an imide (i.e., as in APCCDI), was built upon in a more complex system in which an NDI unit is coupled via imides to two carbazole units to form APCNDI. The electrochemical polymer films formed show reductive and oxidative electrochromism and selective enhancement of Raman bands of the polymer films. We show that complete quenching of the photoluminescence of both NDI and bis-carbazole is achieved, which enables the study of the polymer films formed, and assignment of charge trapping as kinetic or thermodynamic (vide infra), using multiwavelength resonance Raman microspectroscopy under electrochemical control. The APCNDI polymer films formed show reductive and oxidative electrochromism and selective enhancement of Raman bands of the various accessible redox states. We show that oxidative and reductive kinetic charge trapping can be achieved in thicker films and can be “read out” in poly-APCNDI by resonance Raman spectroscopy nondestructively, providing for applications in nonvolatile memory.

attachment. Mass spectra were recorded on a MALDI TOF PerkinElmer FTIR Spectrum 400 equipped with a UATR coupled to LEDs (Thorlabs). FTIR spectra were recorded on a modified solutions or a Nikon TE-Eclipse inverted microscope for fluorophores, using a Shamrock163 spectrograph with a 300 l/mm grating blazed at 300 nm. Emission spectra were obtained using an Andor Newton 970-BV (Andor Technology). Spectra were acquired and processed using Andor Solis and PerkinElmer Spectrum 10.0, respectively. Fluorescence spectra were recorded using quartz cuvettes containing 5 nM solutions of analyte in dichloromethane with excitation provided by a 75 W xenon lamp coupled to a Zolix 135° and 180° backscattering mode, respectively. Raman spectra were recorded at 785 nm using a quartz cuvette as electrochemical cell. Raman spectra were recorded at λexc 266 nm (0.6 mW at sample, obtained by frequency doubling of the 532 nm output of a DPSS laser using a Newport WaveTrain) and 355 nm (10 mW at sample, Cobolt lasers) in a Shamrock500 spectrograph (Andor technology) with a 2400 l/mm grating blazed at 300 nm onto an iDus-420-BU2 CCD (Andor Technology). Spectra were acquired and processed using Andor Solis and PerkinElmer Spectrum 10.0, respectively. Fluorescence spectra were recorded using quartz cuvettes containing 5 nM solutions of analyte in dichloromethane with excitation provided by a 75 W xenon lamp coupled to a Zolix 150 mm monochromator and to a qpod (Quantum Northwest) temperature controlled cuvette holder. The emission was collected at 90° through a fiber optic connected to an iDus-420-OE CCD camera (Andor Technology).

### RESULTS AND DISCUSSION

#### UV/vis Absorbance and Emission Spectroscopy of D1 and D2.

Although the polymerization of carbazole derivatives has been proposed elsewhere, the propensity of N-phenyl carbazole derivatives to undergo oxidative C–C bond formation to form dimers rather than other electrochemical reactions was investigated in the model compounds D1 and compound D2 (Figure 3). Both D1 and D2 are comprised of an aryl N-substituted carbazole unit, however, D2 does not bear the p-bis-amino motif of D1. Although the cyclic voltammetry of D1 (Figure S6) indicates a propensity to undergo dimerization by C–C coupling of the carbazole units, preparative electrolysis resulted in a general decrease in UV absorbance and completely loss in emission intensity (Figure 4 upper). In contrast, cyclic voltammetry (Figure S7) and preparative oxidative electrolysis of solutions of D2 resulted in a minor broadening in the UV/vis absorbance spectrum and a red shift of the emission spectrum consistent with formation of a bis-carbazole (Figure 4 lower). In both cases, there was no indication of formation of polymer films at the working electrodes. The greater stability, with regard to oxidation, of the quinoidal character of the carbazole units, however, does not bear the p-bis-amino motif of D1.

![Scheme 2. One Electron Oxidation of Bis-Aminophenyl Modified Carbazole is Centered on the Carbazole Unit but is Expected to Have Significant Contribution from Resonance Structures Involving the Protected Bis-Aminophenyl Unit, Exposing It to Competing Hydrolysis Reactions](image)

Voyager DE-Pro by Applied Biosystems and a Xevo G2 Q-TOF DART by Waters Corporation. In situ Resonance Raman spectroelectrochemistry was performed following electropolymerization on a platinum disc working electrode by repeated cyclic voltammetry, followed by washing of the polymer modified electrode with dichloromethane and immersion in dichloromethane with 0.1 M TBAH. In situ measurements were performed on a PerkinElmer Raman station with excitation at 785 nm using a quartz cuvette as electrochemical cell. Raman spectra were recorded at λexc 266 nm (0.6 mW at sample, obtained by frequency doubling of the 532 nm output of a DPSS laser using a Newport WaveTrain) and 355 nm (10 mW at sample, Cobolt lasers) in 135° and 180° backscattering mode, respectively. Raman scattering was collimated and subsequently refocused by a pair of 25 mm planoconvex lenses (7.5 and 15 mm focal lengths, respectively) into a Shamrock500 spectrograph (Andor Technology) with a 2400 l/mm grating blazed at 300 nm onto an iDus-420-BU2 CCD (Andor Technology). Spectra were acquired and processed using Andor Solis and PerkinElmer Spectrum 10.0, respectively. Fluorescence spectra were recorded using quartz cuvettes containing 5 nM solutions of analyte in dichloromethane with excitation provided by a 75 W xenon lamp coupled to a Zolix 150 mm monochromator and to a qpod (Quantum Northwest) temperature controlled cuvette holder. The emission was collected at 90° through a fiber optic connected to an iDus-420-OE CCD camera (Andor Technology).

![Figure 3. Model compounds used to study carbazole oxidative dimerization, N-(p-carbazole phenyl)acetamide (D1), and methyl p-carbazole benzoate (D2), amino-phenyl carbazole cyclohexane imide (A1), amino-phenyl carbazole cyclohexane imide (I1), and its dimer obtained by chemical oxidation (I2).](image)
motif is important and reaction of this moiety after oxidation may compete effectively with carbazole dimerization.

Compound I1, prepared from APC (aminophenyl carbazole) by reaction with cyclohexyl-1,2-dicarboxy anhydride was dimerized by chemical oxidation64,65 to yield model compound I2. Dimerization of I1 to form I2 results in broadening of the UV absorption bands and a redshift in the emission (Figure 5), as observed for D1/D2.

The retention of the absorption and emission properties upon oxidative coupling of I1 to form I2 indicates that the diimide connection prevents involvement of the p-bis-amino motif in the redox chemistry of the compounds. Hence the structure APCCDI, prepared analogously to I1 (see SI), was expected to undergo sequential oxidative dimerization of the imide-linked phenyl carbazoles (Scheme 1).

Indeed the cyclic voltammetry of APCCDI is as expected for an indole containing compound,35−37 i.e., a 4-electron ECCE process resulting in dimerization via aryl−aryl coupling (Figure 6). Two carbazole radical cations, formed an electrochemically, couple and undergo double deprotonation to rearomatize. This process is followed by immediate oxidation to the product’s doubly cationic state at the applied potential, with two new redox waves on the return cycle assigned to the first and second reductions of the [bis-carbazole]2+ units formed.

In contrast to compound I1, however, dimerization leaves two carbazole units connected via the diimide bridges, which can undergo subsequent coupling to other carbazole units and hence stepwise chain elongation. The oligomers are insoluble and deposit on the electrode surface readily leading to the buildup of a redox polymer manifested in the steady increase in current (Ip,a and Ip,c) of the redox waves of the bis-carbazole unit (Figure 7). Importantly the oxidation potential of APCCDI is close to that of the second oxidation of the bis-carbazole unit formed and hence film growth is not limited by lack of conductivity at the onset potential for polymerization. The voltammetry of polymer modified electrode in monomer free solution shows the redox waves of poly-APCCDI, indicating that the polymer is well adhered to the electrode surface and is not affected substantially by the presence adventitious water or oxygen. Films from poly-APCCDI were formed readily at glassy carbon, platinum, and ITO on glass slide electrodes indicating that surface polymer interactions are not especially important in achieving adhesion, but instead that solubility is the primary driving force.

Figure 4. (Top left) UV/vis absorbance and (top right, λexc 300 nm) emission spectra of D1 before (black) and after preparative anodic electrolysis (black dotted) at 1.2 V for 15 min. (Bottom left) UV/vis absorbance and (bottom right, λexc 300 nm) emission spectra of D2 in dichloromethane (solid line) before and after preparative anodic electrolysis (dotted line) at 1.2 V for 1 h. (Bottom right) Emission spectra showing change in relative emission intensity and normalized spectra. Conditions: in dichloromethane with 0.1 M TBAPF6, with a carbon mesh working, SCE reference and platinum counter electrode.
Electrochemical Modulation of poly-APCCDI Fluorescence. The fluorescence of poly-APCCDI was expected to be similar to that of I2, however, immobilization in a polymer film at a, e.g., Au, macroelectrode could result in emission quenching due to intermolecular interactions. The emission of poly-APCCDI, excited at $\lambda_{\text{exc}}$ 365 nm, was less well-defined (broader) than that of I2, but is nevertheless, together with its slight red-shift, typical for the bis-carbazole motif. Oxidation resulted in complete quenching of photoluminescence with full recovery upon reduction to the neutral state (Figure 8). Monitoring of photoluminescence switching during multiple potential steps shows that relatively rapid switching on and off of polymer emission with a response time that indicated charge diffusion was limiting (vide infra).

Multiresponsive Bis-Carbazole Based Redox Polymer Films Incorporating Naphthalene Diimide. The versatility of the bis-imide bridging motif in APCCDI, prompted the incorporation of a naphthalene unit to increase functionality and the preparation of APCNDI (for details of synthesis and characterization, see SI, and Figure S16). The absorption spectrum of APCNDI shows the characteristic vibronic progression ($\pi-\pi^*$ transition) of the naphthalene diimide with maxima at 320, 340, 360, and 380 nm, which overlap with the lowest $\pi-\pi^*$ transitions of the carbazole moiety (Figure 9). The absorption bands are shifted bathochromically compared with the precursor 1,4,5,8-naphthalenetetracarboxylic dianhydride (NDA). At $\lambda_{\text{exc}}$ 266 nm, the emission spectrum of an equimolar mixture of NDA and p-CMBz is dominated by carbazole emission (Figure 9), consistent with the large difference in molar absorptivity of the components. At $\lambda_{\text{exc}}$ 355 nm, the emission from both components is similar in intensity. In contrast, the APCNDI shows essentially no emission upon excitation at either wavelength with only Raman scattering from solvent observed, indicating highly efficient emission quenching, considering the components redox chemistry (vide infra), by photoinduced electron transfer (PET) from the carbazole to the naphthalene moieties (Scheme 3). Importantly, the extent of quenching seen in these data confirm the absence of unreacted NDA and the carbazole precursor in APCNDI and contrasts sharply with that observed for the naphthalene bis-carbazole system reported by Koyuncu, in which emission was observed and even increased 3-fold with subsequent electro-polymerization.

Resonance Raman Spectroscopy of APCNDI. The strong blue emission of both carbazole and naphthalene diimide precludes the application of resonance Raman spectroscopy with excitation in the 250–400 nm range (vide supra and Figure S19). The highly efficient photoinduced electron transfer quenching from the carbazole to the NDI...
moiety observed in APCNDI, however, allows resonance Raman spectra to be recorded in dilute solutions at $\lambda_{\text{exc}}$ 266 and 355 nm (Figure 10). Enhancement of Raman bands at 1625 and 1237 cm$^{-1}$ corresponding to those observed in the Raman spectra of carbazole is seen at $\lambda_{\text{exc}}$ 266 nm and assigned to aromatic ring stretch and C$\equiv$N stretch vibrations, respectively, of the carbazole moiety only (since the NDI unit does not absorb significantly at this wavelength and indeed NDA shows only very weak resonance enhancement at $\lambda_{\text{exc}}$ 266 nm, Figure S20). The carbazole in plane bending modes at 1178 and 1019 cm$^{-1}$, and out of plane bending mode at 705 cm$^{-1}$ were also observed. Resonance enhancement of both the naphthalene

Figure 7. (Left) Cyclic voltammetry of APCCDI (0.1 mM) at a Au electrode (d = 3 mm), and (right) cyclic voltammetry of the poly-APCCDI modified electrode in a monomer free solution. In dichloromethane, 0.1 M TBAPF$_{6}$, Pt counter, and SCE working electrode, scan rate 0.1 V s$^{-1}$, final surface coverage is estimated to be $2.4 \times 10^{-8}$ mol cm$^{-2}$ on the basis of the anodic charge passed.

Figure 8. (upper left) In situ photoluminescence ($\lambda_{\text{exc}}$ = 365 nm) of poly-APCCDI and (upper right) the corresponding cyclic voltammetry of the poly-APCCDI modified Au electrode in dichloromethane (0.1 V s$^{-1}$, 0.1 M TBAPF$_{6}$). Multistep potential switching cycles with alternating polarization at 0 V for 30 s and 1 V for 15 s. SCE reference and platinum counter electrodes.
diimide and carbazole moieties of APCNDI is observed at $\lambda_{\text{exc}}$ 355 nm (Figure 10). The bands at 1724 and 1685 cm$^{-1}$ are assigned to naphthalene C=O stretching, while the carbazole C=C stretch is observed at 1627 cm$^{-1}$ together with bands at 1608 and 1415 cm$^{-1}$ assigned as naphthalene aromatic C=C and C–C stretching modes. Bands at 1111, 1073, and 1033 cm$^{-1}$ are assigned to in-plane, and 713, 657, and 605 cm$^{-1}$ to out-of-plane C–H bending modes of APCNDI. The bands at 1569, 1386, 858, 823, and 537 cm$^{-1}$ are useful in assignment of the resonance Raman spectra of the polymer films formed (vide infra).

**Cyclic Voltammetry of APCNDI.** The redox chemistry of APCNDI between 0.0 and $-1.7$ V vs SCE is typical of an NDI (naphthalene) moiety with two reversible redox processes at $-0.80$ V and $-1.20$ V, with no evidence of polymer film formation even with repeated cycling between 0.0 and $-1.7$ V (Figure 11). The redox chemistry between 0.0 and 1.4 V vs SCE is identical to that of APCCDI, with efficient formation of a redox polymer film, as expected with sequential coupling of each carbazole moiety to build up a film of poly-APCNDI on the electrode. At a scan rate of 0.1 V s$^{-1}$, the cyclic voltammograms can undergo 100 segments while showing a steady increase of the redox response throughout. Although film thicknesses cannot be determined precisely from the redox response, due to incomplete charge transfer due to charge
Figure 10. Resonance Raman spectra (λ<sub>exc</sub> (left) 266 nm and (right) 355 nm) of APCNDI (i) in acetonitrile and (ii) in dichloromethane. *Distortions due to imperfect subtraction of Raman scattering of the solvent.

Figure 11. (Left) Reductive cyclic voltammetry of poly-APCNDI and (center) initial oxidative cyclic voltammetry of APCNDI (0.1 mM) in dichloromethane (0.1 V s<sup>-1</sup>, 0.1 M TBAPF<sub>6</sub>, argon purged, GC working electrode, with iR compensation applied) with assignment of redox processes. (Right) Repeated oxidative cyclic voltammetry of APCNDI showing a steady increase in signal for poly-APCNDI. SCE reference and platinum counter electrodes.

Figure 12. (left) Cyclic voltammetry of a poly-APCNDI modified platinum working electrode in monomer free dichloromethane (with 0.1 M TBAPF<sub>6</sub>). The anodic wave at 0.8 V is due to release of trapped charges (vide infra) from reduction. Cathodic charge trapping, present in complete overlap with the reduction at −0.6 V here, is also observed clearly under monomer free conditions on an ITO working electrode (Figure S22). (Right) Cyclic voltammetry of a poly-APCNDI modified glassy carbon electrode in monomer free dichloromethane. Initial scan toward negative potentials from 0.0 V shows a reversible one electron redox wave (A) with a corresponding discharge peak (B) on the return cycle toward positive potentials which is absent on the second cycle in which the switching potential is 0.3 V. The third consecutive cycle to positive and the negative potentials shows a discharge peak due to trapped positive charges (D) (with 0.1 M TBAPF<sub>6</sub> platinum counter, and SCE reference electrode, scan rate 0.1 V s<sup>-1</sup>). SCE reference and platinum counter electrodes.
trapping (vide infra), an estimation can be made of the upper and lower limits of surface coverage by comparing cathodic and anodic charge passed. The surface coverages determined under these conditions are between 1.2 and 1.6 × 10^{-9} \text{ mol cm}^{-2} at a glassy carbon electrode, which when compared with typical monolayer coverages that are the range of 10^{-10} to 10^{-12} \text{ mol cm}^{-2}, indicates ca. 10 to 15 monolayer equivalents. Discharge peaks are observed during cyclic voltammetry, in monomer containing solution, typically after the third or fourth cycle and grow incrementally thereafter. Surface coverage at this point is estimated to be between 1.5 and 1.8 × 10^{-10} \text{ mol cm}^{-2}, which is in the order of a one to two monolayers.

The redox response of the poly-APCNDI formed on a range of electrode types is retained upon washing and transferring to monomer free solution (Figure 12) and are stable under repeated cycling between 0.2 and 1.2 V, confirming the chemical and mechanical robustness of the films, i.e., with regard to adventitious water and oxygen. Notably, when performing cyclic voltammetry over the potential range of both redox-active species, i.e., between −1.0 and 1.4 V, a prepeak to either or both of the cathodic and anodic processes appears (Figure 12). This occurrence was assigned to charge trapping, the characterization of which will be discussed below. A linear dependence of current of the main redox waves on scan rate (up to 2 V s^{-1}) is observed as expected for a surface confined redox process (Figure S21).

**UV/vis–NIR Absorption Spectroelectrochemistry of poly-APCNDI.** The UV/vis absorption spectrum of poly-APCNDI resembles that of the monomer with the characteristic vibronic structure of the naphthalene diimide unit redshifted slightly (Figure S23). UV/vis absorption spectra of poly-APCNDI on an ITO on glass electrode in several oxidation states are shown in Figure 13. Reduction results in the appearance of a characteristic absorption band at 480 nm corresponding to the NDI monoanion (at −0.90 V), concomitant with a decrease in the absorbance of the NDI unit at 390 nm. At more negative potentials, a band at 425 nm appears corresponding to the NDI dianion (at −1.40 V), concomitant with a decrease in the absorbance of the NDI monoanion at 480 nm (Figure 13). Complete conversion to the NDI dianion, i.e., a complete loss in absorbance of the NDI monoanion at 710 and 790 nm, was not achieved, indicating that Coulombic interactions are not fully compensated by uptake of cations (TBA^+) from the electrolyte. Scaled subtraction of the UV/vis absorption spectrum of the NDI monoanion reveals the absorption spectrum of the NDI dianion (Figure S24). Notably, subsequent oxidation at 0.0 V does not lead to a full recovery of the original absorption spectrum with residual absorbance of the NDI monoanion consistent with kinetic charge trapping in the film (Figure S25, vide infra). UV/vis spectra recorded during cyclic voltammetry between 0.00 to 1.60 V showed the appearance of NIR absorptions assigned to the monocationic (425 and 1200 nm, at 1.0 V, Figure S26) and dicationic (775 nm, at 1.5 V) states of the bis-carbazole units (Figure 13) and a decrease in bis-carbazole absorption at 325 nm. The absorbance of the NDI unit is unaffected by oxidation. The combination of NDI and APC units allow for access to five distinct redox states and control of absorption over the entire UV/vis–NIR spectral range, and in particular the visible region which is not accessed easily with polymers comprising of carbazole units alone.

**Resonance Raman Spectroelectrochemistry of poly-APCNDI.** In situ Raman spectroscopy, at \( \lambda_{\text{exc}} \) 785 nm allowed for characterization of the APCNDI monocation, dication, and monoanion states, making use of resonance enhancement due to the absorption of these states at this wavelength (Figure S21, vide infra). Continuous monitoring by Raman spectroscopy during cyclic voltammetry on a polymer modified platinum electrode between 0.20 and 1.30 V shows the appearance of weak bands at 1622, 1592, and 702 cm^{-1} upon oxidation between 0.7 and 1.0 V. At potentials above 1.1 V, additional bands were enhanced substantially also together with a change in the relative intensity of the bands at ca. 1600 cm^{-1}. These bands disappeared upon subsequent reduction. The increased intensity observed for the dication state compared with that for the monocation state is consistent with the increased absorbance at 785 nm for the former (Figure 13). The relative intensity of the bands of the weakly scattering monocationic species allows them to be distinguished easily from those of the dicationic species and are in both cases assigned to the bis-carbazole unit.

The resonance enhanced Raman bands (at \( \lambda_{\text{exc}} \) 266 nm) of APCNDI at 1622 and 705 cm^{-1} (Figure 10) are assigned to C=C stretching and C–H out of plane bending of the carbazole moieties and correspond with bands observed for the mono- and dication states of poly-APCNDI. The bands at 1172...
Furthermore, a shoulder at 1653 cm$^{-1}$, and 618 cm$^{-1}$, close to the band observed at 1237 cm$^{-1}$, 1164, 1140, and 1092 cm$^{-1}$, indicates a dicationic state. In the case of the dicationic state, the bands at 704 cm$^{-1}$, shifts to 712 cm$^{-1}$ upon oxidation, while the stronger band shifts from 1594 to 1599 cm$^{-1}$, assigned to in plane bending of the oxidized carbazole C$\equiv$H modes. Additionally, the appearance of a band at 1269 cm$^{-1}$ was assigned as a C$\equiv$N stretching mode, which is close to the band observed at 1237 cm$^{-1}$ in the spectrum of the monomer (at $\lambda_{\text{exc}}$ 266 nm), the shift to higher wavenumber being consistent with the increased bond strength expected in the cationic state (i.e., increased C$\equiv$N character). The carbazole C$\equiv$C stretching band at 1622 cm$^{-1}$ is unchanged upon oxidation, while the stronger band shifts from 1594 to 1599 cm$^{-1}$ (also observed in the ex situ Raman measurements, vide infra) and gains intensity relative to the 1622 cm$^{-1}$ band. Furthermore, a shoulder at 1653 cm$^{-1}$ is observed in the monocationic state, assigned to the C$\equiv$C alkene stretch due to loss of aromaticity through the radical character of the monocation. The band at 704 cm$^{-1}$ observed for the monomer at $\lambda_{\text{exc}}$ 266 nm, assigned to a C$\equiv$H out of plane bending mode of APCNDI, shifts to 712 cm$^{-1}$ upon further oxidation to the dicationic state. In the case of the dicationic state, the bands at 1164, 1140, and 1092 cm$^{-1}$ are assigned as in plane, and 675, 651, and 618 cm$^{-1}$ as out of plane C$\equiv$H bending modes, constituting shifts of up to 30 cm$^{-1}$ from those modes observed in resonance Raman spectrum of the monomer.

**Charge Trapping in poly-APCNDI Films.** In contrast to APCCDI, for APCNDI a prepeak to both oxidation and reduction waves was observed on a range of electrodes (including glassy carbon, platinum, and gold macroelectrodes and ITO coated glass slides), indicative of charge trapping. For example, at a gold macroelectrode, additional redox waves were observed at 0.80 V and at $\sim$0.50 V during formation of poly-APCNDI in the cyclic voltammetry of APCNDI (Figure 15). Charge trapping was first reported by Murray et al. in 1981 and is due to the confinement of charges in the polymer film through defects (i.e., thermodynamic—where a distinct species with a redox potential less positive or less negative than the polymer is formed) or where the outer layer is unable to discharge before the inner layer is depolarized (i.e., kinetic—where polymer film is sufficiently thick that the inner layer insulates the outer layer from the potential gradient at the electrode, Figure 15).

The increase in the discharge peak current and shift to more positive/negative potential with cycle number and hence film thickness are apparent during the polymerization of APCNDI by cyclic voltammetry (Figure 15). These shifts reflect an increase in the distance between the outer edge of the polymer film and the limit to the thickness of film at the electrode that can be discharged directly. This, however, does not imply that charge trapping does not occur in films of poly-APCNDI (vide supra), albeit that the trapped positive charges are not released by film reduction due to the absence of an accessible reduction wave. The formation and release of trapped charges can be observed by cyclic voltammetry, UV/vis absorption (Figure 13), and resonance Raman spectroscopy providing dual redox-functionality of electrochromism and nonvolatile 3-state memory (reduced, neutral, oxidized).

Raman spectra recorded at a poly-APCNDI modified Au electrode enables identification of the species responsible for the charge trapping, with spectra recorded, ex-situ, of charged films showing Raman bands that confirm that the species responsible for charge trapping are in both cases the one electron oxidized and reduced states (Figure 16).

C$\equiv$C stretching modes at 1620 and 1594 cm$^{-1}$ are observed, which correspond to a one electron oxidized bis-carbazole species. The spectrum of the positively charge trapped film shows a shoulder at 1620 cm$^{-1}$ and a shift toward 1594 cm$^{-1}$ by the scattering maximum at 1598 cm$^{-1}$. Additionally, Raman bands at 1341, 1267, 718, and 588 cm$^{-1}$ appear both upon oxidation and in the film that had undergone a cycle to positive potentials and subsequently to 0.0 V. Upon both reduction of the polymer film and after a reductive cycle in which the potential is returned to 0.0 V, bands at 1413 and 1374 cm$^{-1}$ are observed. Furthermore, these bands decrease in intensity concomitantly with the appearance bis-carbazole monocation modes upon oxidation. The band at 1413 cm$^{-1}$ is assigned to a naphthalene aromatic C$\equiv$C stretching by comparison with the resonance Raman spectrum of APCNDI monomer recorded at $\lambda_{\text{exc}}$ 355 nm. Similarly, the bands at 541 and 1374 cm$^{-1}$ correspond to those at 537 and 1386 cm$^{-1}$, respectively, in APCNDI. Hence, positive or negative charges trapped in the polymer film can be assigned as due to kinetically trapped cationic and anionic forms of the bis-carbazole and NDI moieties, respectively.

Erasing and rewriting this three state charge trapping system can be achieved by application of positive and negative potentials and subsequently to 0.0 V. Upon both reduction of the polymer film and after a reductive cycle in which the potential is returned to 0.0 V, bands at 1413 and 1374 cm$^{-1}$ are observed. Furthermore, these bands decrease in intensity concomitantly with the appearance bis-carbazole monocation modes upon oxidation. The band at 1413 cm$^{-1}$ is assigned to a naphthalene aromatic C$\equiv$C stretching by comparison with the resonance Raman spectrum of APCNDI monomer recorded at $\lambda_{\text{exc}}$ 355 nm. Similarly, the bands at 541 and 1374 cm$^{-1}$ correspond to those at 537 and 1386 cm$^{-1}$, respectively, in APCNDI. potentials (Figure 17). Reduction of the film followed by polarization of the electron to 0.0 V resulted in the appearance of a discharge peak on cycling to positive potentials even after a 30 min delay.

**CONCLUSIONS**

The design of multifunctional surfaces and especially redox functional surfaces based on molecular components necessitates the proper orthogonal functioning of not only the “active” components but also the components required for polymer film formation. In this contribution, we show that oxidative C–C coupling of carbazole is a versatile approach to the formation of stable redox polymer films when two carbazole units are tethered appropriately so as to enable sequential dimerization and thereby stepwise polymer growth. The key advantage to the bis-carbazole unit in polymer film formation is that the redox potential for the oxidation of monomer is coincident with that of the second oxidation of the bis-carbazole unit, thereby avoiding film growth limitations seen with earlier systems. The unit connecting the two carbazole units is key to achieving this and in the present study an amino phenyl unit helps to lower the redox potential of the carbazole unit, however, the use of a diimide group in the bridge is

Figure 15. poly-APCNDI film formation via repetitive cyclic voltammetry at a gold macroelectrode (0.067 mM in dichloromethane with 0.1 M TBAPF$_6$, scan rate 0.1 V s$^{-1}$, inert atmosphere, with Ag/AgCl reference and Pt counter electrode). Left: initial cycle(s) and right: later cycles. The prepeaks “X” are due to discharge of kinetically trapped charges.

Figure 16. Ex situ Raman spectroscopy ($\lambda_{\text{exc}}$ 785 nm) of a poly-APCNDI modified Au working electrode. Recorded states include the discharged (by cycling to $-0.5$ and 0.8 V in order to release negatively (left) and positively (right) trapped charges, respectively, solid black lines), charge trapped (by cycling to $-0.9$ V (left) or 1.1 V (right) and back, blue, and red lines), and fully charged state (by pausing the cyclic voltammogram at either $-0.9$ (left) or 1.1 (right) V, cyan and orange lines). In dichloromethane with 0.1 M TBAPF$_6$ at a scan rate of 0.5 V s$^{-1}$.
Figure 17. Sequential cyclic voltammetry of a gold macro electrode poly-APCNDI modified film in monomer free solution (dichloromethane with 0.1 M TBAPF6, scan rate 0.1 V s"−1, with Ag/AgCl reference and Pt counter electrode, “n-charging” carried out by a reductive cycle to −0.9 V). Cyclic voltammograms were recorded of a charged film, read-out after 30 min storage in air while charged, a subsequently discharged film, and thereafter immediately recharged film. Similar data showing charge storage over 6 days is shown in Figure S27.

essential to preclude interference by the formally, p-diaminobenzene motif. The various precursors led to the design of the multifunctional electro-polymerizable unit through insertion of an additional redox active naphthalene group to form APCNDI. Interestingly, whereas poly-APCCDI shows redox switchable photoluminescence, the APCNDI Donor—Acceptor—Donor system exhibits complete quenching of emission through intramolecular photoinduced electron transfer between the NDI and APC moieties. The quenching is sufficient to enable characterization of poly-APCNDI films in several redox states by resonance Raman spectroscopy. In particular, we demonstrate that charge trapping in sufficiently thick films of poly-APCNDI is kinetic and not thermodynamic.

Although resonance Raman spectroscopy is used in the present study primarily to characterize the species responsible for charge trapping as kinetic and not thermodynamic, read can be achieved by UV/vis absorption spectroscopy and electrochemically. However, although a possible advantage of Raman microspectroscopy is found in the specificity of the molecular information contained within the spectra and high spatial resolution, ultimately charge trapping is useful in electrical readout systems despite the destructive nature of such readout. In summary, the combination of facile polymer film formation with highly controllable film thickness together with retention of the properties of the monomer APCNDI in the films, provide for a 3-state nonvolatile memory with nondestructive optical readout and by resonance Raman spectroscopy.
