ABSTRACT

We derive the total cold gas, atomic hydrogen, and molecular gas masses of approximately 24,000 galaxies covering four decades in stellar mass at redshifts $0.5 < z < 3.0$, taken from the CANDELS survey. Our inferences are based on the inversion of a molecular hydrogen based star formation law, coupled with a prescription to separate atomic and molecular gas. We find that: 1) there is an increasing trend between the inferred cold gas (HI and H$_2$), HI, and H$_2$ mass and the stellar mass of galaxies down to stellar masses of $10^8 M_\odot$ already in place at $z = 3$; 2) the molecular fractions of cold gas increase with increasing stellar mass and look-back time; 3) there is hardly any evolution in the mean HI content of galaxies at fixed stellar mass; 4) the cold gas fraction and relative amount of molecular hydrogen in galaxies decrease at a relatively constant rate with time, independent of stellar mass; 5) there is a large population of low-stellar mass galaxies dominated by atomic gas. These galaxies are very gas rich, but only a minor fraction of their gas is molecular; 6) the ratio between star-formation rate (SFR) and inferred total cold gas mass (HI + H$_2$) of galaxies (i.e., star-formation efficiency; SFE) increases with star-formation rate at fixed stellar masses. Due to its simplicity, the presented approach is valuable to assess the impact of selection biases on small samples of directly-observed gas masses and to extend scaling relations down to stellar mass ranges and redshifts that are currently difficult to probe with direct measurements of gas content.

Key words: galaxies: evolution - galaxies: formation - galaxies: ISM - ISM: molecules

1 INTRODUCTION

Observations in the local Universe have revealed that star formation (SF) is closely linked to the density of molecular gas. SF in the Milky Way takes place in dense, massive and cold giant molecular clouds (Solomon et al. 1987; McKee & Ostriker 2007; Bolatto et al. 2008). Recent works have emphasized that there is a strong correlation between the star-formation rate (SFR) density and the density of molecular hydrogen (H$_2$), while the correlation with the density of atomic hydrogen (H1) is weak or absent (Wong & Blitz 2002; Bigiel et al. 2008; 2011; Schruba et al. 2011). These results have stimulated the idea that not all the cold gas in a galaxy is necessarily available for SF. A proper understanding of the evolution of the atomic and molecular gas

* E-mail: gpopping@eso.org
content of galaxies is a key ingredient that will shed light on the physics that regulates the stellar buildup of galaxies. Current surveys of the cold gas content of galaxies at high redshift only probe the molecular gas mass and are usually limited to massive galaxies with high SFR (e.g., Daddi et al. 2010; Tacconi et al. 2010; Geach et al. 2011; Baner­meister et al. 2013; Tacconi et al. 2013; Santini et al. 2013). It is crucial to include the contribution from atomic hydrogen to thoroughly understand how the total cold gas properties of galaxies regulate the SFR. Furthermore, for a complete assessment it is necessary to study a galaxy sample that is not biased to the most actively star-forming objects. It is hoped that facilities such as ALMA (Atacama Large Millimeter Array), NOEMA (Northern Extended Millimeter Array), SKA (Square Kilometer Array), MeerKat (Karoo Array Telescope) and ASKAP (Australian SKA Pathfinder) will reveal the H I and H 2 content of representative samples of high-redshift galaxies.

Theorists have made considerable progress developing models that track the H I and H 2 content of galaxies (Obreschkow & Rawlings 2009; Fu et al. 2010; Krumholz & Dekel 2012a; Lagos et al. 2011; Christensen et al. 2012; Kuhlen et al. 2012; Davé et al. 2013; Popping, Somerville & Trager 2014; Somerville, Popping & Trager 2015). These models have proven successful at reproducing the available observational estimates of the overall H I and H 2 properties of local and high-redshift galaxies. Nevertheless, observational constraints at high redshift are still very limited and do not probe the wide parameter space covered by the models. Additional information on the gas content of galaxies will be crucial to break the degeneracies in different physical mechanisms that are included in models (e.g., SF and stellar feedback).

In the meantime, we can obtain indirect constraints on the gas content of galaxies by using the empirical relation between SFR density and gas density. This approach has been used extensively by inverting the Schmidt-Kennicutt relation (Kennicutt 1998; hereafter the KS-relation), which relates the SFR surface density to the combined atomic and molecular hydrogen surface density (e.g., Erb et al. 2006; Mannucci et al. 2009; Troncoso et al. 2013). Popping et al. (2012) were the first to use an inverted molecular-gas-based SF law in combination with a recipe to separate atomic from molecular hydrogen (Blitz & Rosolowsky 2006) to estimate the total cold gas and molecular gas content of galaxies. This approach was motivated by observations demonstrating that SFR surface densities correlate almost linearly with molecular gas surface density (even in the low gas surface density regime), whereas the KS-relation breaks down at low ‘total gas’ surface densities (Bigiel et al. 2008; Schruba et al. 2011). Popping et al. (2012) showed that, when inferring gas masses, a molecular-gas-based SF law in combination with a prescription to separate the atomic and molecular hydrogen content of galaxies is better suited to reproduce directly-observed gas masses and gas surface densities from a sample of galaxies taken from Leroy et al. (2008) than the total-gas KS-relation.

Popping et al. (2012) confirmed previously observed trends between galaxy gas fraction and molecular gas fraction with stellar mass (e.g., Tacconi et al. 2010; Saintonge et al. 2011), through a detailed study of the inferred gas content of galaxies in COSMOS (the Cosmic Evolution Survey Scoville et al. 2007) at 0.5 < z < 2.0. This initial study suggested that massive galaxies have lower gas fractions at higher redshift than less-massive objects and have lower fractions of their gas in molecular form.

In this paper, we apply the method developed in Popping et al. (2012) and updated in Popping, Behroozi & Peeples (2015) to a galaxy sample drawn from the CANDELS survey (Cosmic Assembly Near-infrared Deep Extragalactic Legacy Survey; Grogin et al. 2011; Koekemoer et al. 2011) at redshifts 0.5 < z < 3. We focus on the cold gas (H I + H 2), H I, and H 2 properties of galaxies over cosmic time and how they are related to the SF and other global properties of galaxies. The CANDELS survey is deeper than the COSMOS survey, which allows us to study much fainter objects. As such, we can probe the gas properties of the bulk of star-forming galaxies between z = 0.5 and z = 3. This cosmic epoch marks the peak in star-formation activity of our Universe (Hopkins & Beacom 2006; Madau & Dickinson 2014), when the bulk of mass in today’s massive galaxies was formed. CANDELS provides exquisite imaging covering a wide range of wavelengths to derive stellar masses and SFR and provides reliable morphological information at these redshifts. The methodology enables us to infer the gas, H I, and H 2 masses for a large number of galaxies covering a wide range in stellar masses, SFRs, sizes, and redshift.

This makes the applied method very helpful in assessing the impact of selection biases on much smaller samples for which direct gas measurements have been obtained. Furthermore, it can extend scaling relations to a stellar mass and redshift range difficult to reach through direct observations of gas masses. The inferred gas masses presented in this work have a great predictive power for future H I surveys such as LADUMA (Holwerda, Blyth & Baker 2012) with instruments like MeerKat, ASKAP, and the SKA and future surveys of the molecular hydrogen content of galaxies through CO or sub-mm continuum imaging with for example ALMA and NOEMA.

This paper is organised as follows. In Section 2 we summarise our method to indirectly measure the cold gas and H 2 content of galaxies and we present the galaxy sample selection from CANDELS. In Section 3 we present our results. The assumptions that were made and the applicability of our model to the CANDELS galaxy sample are discussed in Section 4. We discuss our results in Section 5. We summarise our findings in Section 6. Throughout the paper, we assume a Λ Cold Dark Matter (ΛCDM) cosmology with H 0 = 70 km s −1 Mpc −1, Ω matter = 0.28 and Ω Λ = 0.72 (Komatsu et al. 2009). We assume a universal Chabrier stellar initial mass function (IMF: Chabrier 2003) and where necessary convert observational quantities used to a Chabrier IMF. All reported cold, H I, and molecular gas masses include a correction of 1.36 to account for helium.

2 MODEL & DATA

In this section we describe our method to indirectly estimate the cold gas (H I + H 2), H I, and H 2 content of galaxies and the observational data to which we apply our method.
2.1 Obtaining indirect gas measures

We infer the cold gas (H1 + H2), H1 and H2 content of galaxies using a combination of an empirical molecular SF law (based on Bigiel et al. 2008) and a prescription to calculate the H2 fraction of cold gas (Blitz & Rosolowsky 2006). To infer the H1 and H2 masses of a galaxy we only use the galaxy stellar mass, SFR, and size as input parameters. We pick a gas mass, distribute the gas as explained in the next paragraph, and then calculate a SFR for that gas mass following the equations given below. We repeat this process while iterating through gas masses till convergence with the observed SFRs is reached. When convergence is reached we separate the cold gas mass into an atomic and molecular component using equation [3].

We assume the galaxy stellar mass to be distributed following a S´ersic profile Σ∗(r) ∝ exp[−(r/r∗)1/n], where r∗ is the scale radius of the stellar disc for a S´ersic profile and n the S´ersic index of the galaxy. We also assume that the gas in galaxies is distributed following the same S´ersic profile, with a scale radius

\[ r_{\text{gas}} = \chi_{\text{gas}} r_{\ast}, \]

where \( \chi_{\text{gas}} \) is the scale radius of the gas disc relative to the stellar disc. We take \( \chi_{\text{gas}} = 1.7 \) based on a fit to the galaxy disc profiles presented in Leroy et al. (2008).

We use a slightly adapted version of the star formation law deduced by Bigiel et al. (2008) to allow for higher star formation efficiencies in high gas surface density regions. This is based on the results of Daddi et al. (2010) and Genzel et al. (2010), who found the star-formation at high surface densities to follow the KS relation (a power-law slope of 1.4 versus 1.0 for Bigiel et al. 2008). The resulting equation is given by

\[ \Sigma_{\text{SFR}} = \frac{A_{\text{SF}}}{10M_{\odot} \text{pc}^{-2}} \left( 1 + \frac{\Sigma_{H_2}}{\Sigma_{\text{crit}}} \right)^{N_{\text{SF}}} f_{H_2} \Sigma_{\text{gas}} \]

where \( \Sigma_{\text{SFR}} \) and \( \Sigma_{\ast} \) are the star formation and cold gas surface densities in \( M_\odot \text{yr}^{-1} \text{kpc}^{-2} \) and \( M_\odot \text{pc}^{-2} \), respectively; \( A_{\text{SF}} \) is the normalization of the power law in \( M_\odot \text{yr}^{-1} \text{kpc}^{-2} \); \( \Sigma_{\text{crit}} \) is a critical surface density; \( N_{\text{SF}} \) is an index which sets the efficiency; and \( f_{H_2} = \Sigma_{H_2} / (\Sigma_{\text{HI}} + \Sigma_{H_2}) \) is the molecular gas fraction. Following Popping et al. (2012), we use \( N_{\text{SF}} = 0.5 \) and we take \( \Sigma_{\text{crit}} = 70 M_\odot \text{pc}^{-2} \).

We use a pressure-regulated recipe to determine the molecular fraction of the cold gas, based on the work by Blitz & Rosolowsky (2006). They found a power-law relation between the midplane pressure acting on a galaxy disc and the ratio between molecular and atomic hydrogen, i.e.,

\[ P_{H_2} = \left( \frac{\Sigma_{H_2}}{\Sigma_{\text{HI}}} \right) = \left( \frac{P_m}{P_0} \right)^{\alpha} \]

where \( P_0 \) is the external pressure in the interstellar medium where the molecular fraction is unity; \( \alpha \) is the power-law index; and \( P_m \) is the midplane pressure acting on the galaxy disc. We adopted \( P_0 = 3.25 \times 10^{9} \text{erg cm}^{-3} \) and \( \alpha = 0.8 \) from Leroy et al. (2008). The midplane pressure can be described by (Elmegreen 1989)

\[ P_m(r) = \frac{\pi}{2} G \Sigma_{\text{gas}}(r) [\Sigma_{\text{gas}}(r) + f_\ast(r) \Sigma_\ast(r)] \]

where \( G \) is the gravitational constant, \( r \) is the radius from the galaxy centre, and \( f_\ast(r) \) is the ratio between \( \sigma_{\text{gas}}(r) \) and \( \sigma_\ast(r) \), the gas and stellar vertical velocity dispersion, respectively. Following Fu et al. (2010), we adopt \( f_\ast(r) = 0.1 \sqrt{\Sigma_\ast(r)/M_\odot} \), where \( \Sigma_\ast(r) \equiv m_\ast/(2\pi r^2) \), based on empirical scalings for nearby disc galaxies. Putting this together, we have an expression for the star formation surface density in Equation (2) depending on the cold gas surface density and stellar mass surface density. We integrate the SFRs in the individual annuli to obtain a total SFR which can be compared to the observed SFR.

We calibrated our method using direct observations of the H1 and/or H2 content of galaxies in the local and high-redshift Universe from Leroy et al. (2008), Daddi et al. (2010), Tacconi et al. (2010), and Tacconi et al. (2013). Using χ-minimization, we find the best agreement between predicted and observed gas masses when adopting a value of \( A_{\text{SF}} = 9.6 \times 10^{-3} M_\odot \text{yr}^{-1} \text{kpc}^{-2} \). This value is close to normalizations found in Bigiel et al. (2008) and Bigiel et al. (2011), 8.42 \times 10^{-3} and 4.6 \times 10^{-3} \( M_\odot \text{yr}^{-1} \text{kpc}^{-2} \), respectively. We integrate the gas disc out to 10 times \( r_{\text{gas}} \). We discuss the uncertainties on some of the individual components of this model in Section 4. The typical systematic uncertainty of our method is 0.3 dex.

A schematic picture of the dependencies of our model is presented in Figure 1. In this figure we explore the effects of changing one of the three input properties of a galaxy (SFR, size, and stellar mass) on the estimated cold gas mass and H2 mass of a galaxy and the cold gas fraction (\( f_{\text{gas}} \)) and molecular hydrogen fraction of the cold gas (\( f_{\text{H2}} \)). We keep two of the parameters fixed and vary the third. Changing the stellar mass of the galaxy has a negligible effect on the inferred cold gas and H2 mass. It is only for the most massive galaxies (\( M_\ast \approx 10^{11} M_\odot \)) that, due to the increased pressure from stars, the inferred cold gas mass decreases and \( f_{\text{H2}} \) increases. Because the inferred cold gas mass remains relatively constant, the cold gas fraction \( f_{\text{gas}} \) rapidly decreases with increasing stellar mass.

We find a strong increase in cold gas mass, H2 mass, \( f_{\text{gas}} \), and \( f_{\text{H2}} \) when increasing the SFR. This is not surprising, as more gas is needed to support the higher SFR. The increased gas mass enhances the cold gas surface density and pressure acting on the gas, which leads to an increase in \( f_{\text{H2}} \). The inferred gas masses increase as a function of scale radius. When increasing the scale radius, the gas densities decrease, therefore the molecular fraction of the gas decreases and the SFR surface density decreases as well. To ensure that convergence with the input SFR is obtained, more gas has to be added to the galaxy to make up for the lowered H2 fractions. This results in high gas fractions and low molecular hydrogen fractions.

2.2 Data

We infer the galaxy gas content of two deep samples of F160W (H-band) selected galaxies from the CANDELS survey at \( 0.5 < z < 3 \) (Grogin et al. 2011; Koekemoer et al. 2011). The CO-to-H2 conversion factor of \( X_{\text{CO}} = 2 \times 10^{20} \text{cm}^{-2} / (\text{K km s}^{-1}) \) Daddi et al. (2010) assumes a CO-to-H2 conversion factor of \( X_{\text{CO}} = 2.25 \times 10^{20} \text{cm}^{-2} / (\text{K km s}^{-1}) \).
Figure 1. Schematic change in cold gas mass, H$_2$ mass, cold gas fraction ($f_{\text{gas}} \equiv M_{\text{gas}}/(M_{\text{gas}}+M_*)$) and molecular hydrogen fractions ($f_{\text{H}_2} \equiv M_{\text{H}_2}/M_{\text{gas}}$) produced by our model when varying the stellar mass (left column), SFR (middle column) and scale radius (right column) of a galaxy. For each column the other two of three input galaxy properties of our model (stellar mass, SFR, and scale radius) are fixed. The fixed values are quoted in the upper panels.

As our method requires us to know the scale radius of each galaxy, we extracted from these catalogues all those sources with good-quality morphological fits in the H band, as determined by van der Wel et al. (2012). We computed the circularized, effective radius $r_e$ of a galaxy as $r_e = a_e \sqrt{b/a}$, where $a_e$ is the effective radius along the major axis and $b/a$ the ratio between the minor and major axis sizes and converted these to the scale length $r_\ast$ for a Sérsic profile with Sérsic index $n$. We converted all scale radii to a common rest-frame wavelength of 5000 Å following van der Wel et al. (2014). Since our model is designed for disc galaxies, we discarded all galaxies with a Sérsic index $n > 2.5$.

We excluded galaxies known to contain an AGN from our sample, to avoid any bias in the derived star formation rates and stellar masses. To identify AGN, we used the 4Ms Chandra X-ray catalogue for the GOODS-S field (Xue et al. 2011), and an infrared power-law spectral energy distribution analysis (Caputi 2013) in the UDS field, as the existing X-ray data is shallow (Ueda et al. 2008). These AGN constitute only 1–2% of the CANDELS $0.5 < z < 3$ samples. It is possible that other galaxies containing an AGN remained in our sample, but the AGN is likely weak as it is not identified in the X-ray data or with the IRAC power-law criterion.

By applying these morphology and AGN cuts, we kept around 60% of the galaxies in the GOODS-S and UDS CANDELS catalogues. The distributions of the $H$-band magni-
Gas evolution in CANDELS galaxies

The [Bruzual 2007] templates have a larger contribution from thermally pulsing asymptotic giant branch (TP-AGB) stars than the [Bruzual & Charlot 2003] templates. Stellar masses calculated based on [Bruzual 2007] are on average 0.1 dex less massive than stellar masses calculated based on the [Bruzual & Charlot 2003] models. Internal dust extinction has been taken into account by convolving all Bruzual and Charlot templates with the [Calzetti et al. 2000] reddening law, with $A_v$ values ranging from 0.0 to 3.0 (with a step of 0.1).

SFRs are based on rest-frame UV fluxes corrected for extinction E(B-V) for each individual galaxy using the [Calzetti et al. 2000] reddening law. UV fluxes were converted into SFRs following [Kennicutt 1998a] for a Chabrier IMF. When IR photometry was available (for just a few percent of our sample) we calculated SFRs based on a combination of non-extinction corrected UV and IR photometry. We derived rest-frame 8µm luminosities from the 24µm fluxes, and converted the 8µm luminosities into total IR luminosities following [Bavouzet et al. 2008]. SFRs were calculated following [Kennicutt 1998a] and [Bell et al. 2005]. In comparison with [Popping et al. 2012] the CANDELS survey is closer to a mass-selected sample and (when IR photometry is available) is based on a more-reliable tracer of the SFR. As such, the results presented in this work supecede our previous efforts.

3 RESULTS

In this section we present galaxy SFRs and the inferred total cold gas, atomic hydrogen, and molecular hydrogen masses of galaxies in the CANDELS survey. We will focus on the gas masses, gas fractions, gas properties of galaxies and the evolution of the gas content of galaxies.

3.1 Galaxy SFR

To fully appreciate the predictive power of our model it is crucial to place the inferred gas masses in their proper context. Our cold gas and H$_2$ estimates depend on the SFR of a galaxy to first order. In Figure 3 we present the SFR of our galaxy sample as a function of stellar mass for different redshift bins. For clarity the relations are shown for the samples taken from the GOODS south field, the UDS field, and the combination of these fields. We find an increasing trend in SFR with stellar mass up to redshifts $z < 3$. The median of this trend has been referred to as the ‘main sequence’ of star-forming galaxies (e.g., [Noeske et al. 2007]; [Elbaz et al. 2011]). The normalization of the trend between stellar mass and SFR decreases with time. At fixed stellar mass, galaxies in the redshift range 2.5 < z < 3.0 formed stars an order of magnitude more rapidly than in the redshift range 0.5 < z < 1.5. At 0.5 < z < 1.0 the increasing trend of SFR with stellar mass has a slope of 0.66. Other studies have found a slope ranging from 0.6 to 1 at the same redshifts ([Pannella et al. 2009]; [Karim et al. 2011]; [Whitaker et al. 2012]; [2014]).

We did not apply any additional selection criteria beyond those described in Section 2.2. While many other studies only select galaxies on the ‘main sequence’ of star-
Figure 3. Galaxy SFR as a function of stellar mass in different redshift bins. The shaded regions show the log of the conditional probability distribution function $P(SFR|M_*)$, which represents the probability distribution of SFRs for fixed stellar masses, and the blue solid and dotted lines show the median fit and 2σ deviation. The left column shows results for the GOODS-S sample, the middle column for the UDS sample, and the right column for the combined GOODS-S and UDS sample. The black line marks the mean trend of the UV + IR based SFRs presented in Barro et al. (2014) in the GOODS-S and UDS fields. The black dashed line marks the double-power-law fit to the relation between stellar mass and SFR presented in Whitaker et al. (2014). We compare our SFRs with SFRs from Barro et al. (2014, black line in Figure 3) and the double power-law fit to the stellar mass – SFR relation presented in Whitaker et al. (2014, black dashed line). We find that our mean trends for the stellar mass – SFR relation are in reasonable agreement with trends found in the literature. We note that Barro et al. (2014) and Whitaker et al. (2014) applied criteria to select actively star-forming galaxies, attempting to exclude more quiescent objects, whereas our selection criteria do not rule out quiescent objects.

There is a large population of galaxies with stellar masses larger than $\sim 10^{10} M_\odot$ and low SFRs ($< 1.0 M_\odot$ yr$^{-1}$). These galaxies with low SFRs are less actively forming stars than counterparts at fixed stellar mass and make up a group of quiescent galaxies (Brennan et al. 2015). For these stellar masses our sample is significantly incomplete (completeness < 50 per cent) below SFRs of $log(SFR/M_\odot$ yr$^{-1}$) = −0.5 at $z = 2$. The SFR limit to observe galaxies increases at higher redshifts. This implies that at redshifts $z > 2.0$ the contribution by galaxies with low SFRs may be larger.

3.2 Cold gas, H1, and H2 content

We present the derived total cold gas masses of our galaxy sample as a function of stellar mass in different redshift bins...
in Figure 4. We find that on average the cold gas mass of a galaxy increases with its stellar mass at all observed redshifts with a sub-linear slope. Despite the clear increasing trend, we do find a significant amount of scatter. Note especially a group of gas-poor galaxies with high stellar masses. This group of galaxies seems to have decoupled itself from the general increasing trend of gas mass with stellar mass, indicating that some physical process has either removed some of the cold gas or prohibits the cooling and/or accreting of gas onto the galaxy. These galaxies are likely on their way towards the red sequence. There is a shift in the normalization in the relation between gas- and stellar-mass with redshift. On average, high-redshift galaxies (especially at $z > 2.0$) are more gas-rich than galaxies with similar stellar mass at lower redshifts. At $0.5 < z < 1.0$ the increasing trend of cold gas mass with stellar mass has a slope of 0.58.

We present the derived H$_2$ masses of our galaxy sample in five redshift bins in Figure 5. Similarly to the total cold gas mass, we find an increase in H$_2$ mass with stellar mass and a decrease in H$_2$ mass with decreasing redshift. We see a group of galaxies with high stellar masses and low H$_2$ masses at $z < 2.5$ in good agreement with a similar group of galaxies seen in the relation between cold gas and stellar mass (Fig. 4). The relation between H$_2$ mass and stellar mass is well defined and has a clear upper envelope over the entire range of stellar masses probed, with only minor stochastic appearance of galaxies above the envelope. The trend between H$_2$ mass and stellar mass is slightly steeper than for the total cold gas mass. At $0.5 < z < 1.0$ the increasing trend of H$_2$ mass with stellar mass has a slope of 0.65. Although the relations between stellar mass and cold
and H$_2$ mass are very similar, there is no simple one-to-one mapping between cold gas mass and H$_2$ mass.

As a comparison we have included direct measures of the H$_2$ mass of galaxies (through their CO luminosity) from the literature (Tacconi et al. 2010; Saintonge et al. 2013) in Figure 5. The mean trend for the inferred H$_2$ masses lies below the observed sample. Our sample contains 24,000 galaxies covering four decades in stellar mass. The observational data points correspond to only a small number of galaxies in a very localized region of parameter space. Our sample was not selected to purely consist of ‘main sequence’ galaxies, driving the mean trends in inferred gas mass down with respect to a galaxy sample consisting of only ‘main sequence’ galaxies only. A close look at Figure 5 shows that most of the directly-observed H$_2$ masses are in good agreement with the most-H$_2$-massive (i.e., actively star-forming) galaxies at stellar masses $M_\ast > 10^{10}$ M$_\odot$.

We find that the increasing relation between stellar mass and H$_2$ mass suggested by the direct observations continues at least down to stellar masses of $10^8$ M$_\odot$.

Figure 5. H$_2$ mass of galaxies as a function of their stellar mass different in redshift bins. The shaded regions show the log of the conditional probability distribution function $P(M_{H_2}|M_\ast)$, and the blue solid and dotted lines show the median fit and one $\sigma$ deviation. Columns are as described in the caption of Figure 3. Purple pentagons, circles, squares, and diamonds are literature values from Daddi et al. (2010), Tacconi et al. (2010), Tacconi et al. (2013), and Saintonge et al. (2013), respectively.

$^2$ Saintonge et al. (2013) calculates the CO-to-H$_2$ conversion factor as a function of metallicity using the prescription presented in Genzel et al. (2012).

$^3$ Tacconi et al. (2013) selected galaxies with a stellar masses $\geq 2.5 \times 10^9$ M$_\odot$ and star-formation rate$\geq 30$ M$_\odot$ yr$^{-1}$. This matches the most-actively star-forming galaxies in our sample.
We show the H I mass of galaxies as a function of their stellar mass in different redshift bins in Figure 6. Like for the cold gas and H2 mass, the H I content of galaxies increases as a function of stellar mass. The scatter around the mean trend is very wide, much wider than trends with cold gas mass and H2 mass. At 0.5 < \( z < 1.0 \) the trend between H I mass and stellar mass has a slope of 0.54.

The relations between stellar mass and cold gas, H I, and H2 mass tightly follow the trend between SF and stellar mass (Figure 3). The well defined upper envelope of this relation for non-starburst galaxies is in good agreement with the upper envelope of the relation between stellar mass and H2 mass. It is important to realize that in our model the H2 mass is to first order a different representation of the SFR of a galaxy (through \( A_{SF} \)), hence the similarity between the slopes of the relation of SFR and H2 mass with stellar mass (0.66 for SFR versus 0.65 for the H2 mass at \( z = 0.5 - 1.0 \)). The total cold gas mass and H I mass are driven through a more complex combination of stellar mass, SFR and disc size, and therefore do not necessarily have a simple relationship with SFR. This is reflected in the difference in the slopes of the relations between stellar mass and SFR (slope of 0.66), cold gas mass (slope of 0.58), and H I (slope of 0.54). The inferred cold gas mass has a slightly shallower increase with stellar mass than the inferred H2 mass and SFR.

### 3.3 Gas fractions

In Figure 7 we show galaxy gas fractions as a function of stellar mass and redshift. There is a strong anti-correlation between galaxy stellar mass and gas fraction at \( z < 2.5 \). The cold gas fraction remains relatively constant at stellar masses \( M* \approx 10^{9.5} M_\odot \) and drops rapidly at higher stellar...
masses for galaxies in our highest redshift bin (2.5 < z < 3.0). In the lower redshift bins the trend between stellar mass and cold gas fractions is roughly linear, mainly driven by a decrease in the cold gas fractions of galaxies with stellar masses 10^9−10 M⊙. The characteristic mass above which the gas fractions rapidly drop (M∗ ≈ 10^{9.5−10} M⊙) suggests that some physical process prevents the buildup of large gas reservoirs in galaxies with a stellar mass above this characteristic mass, and is similar to the quenching mass scale (Kauffmann et al. 2003). We find the strongest evolution in galaxy cold-gas fraction in intermediate mass galaxies (10^9−10 M⊙). At a fixed stellar mass, a galaxy's cold-gas fraction decreases with time.

We present f_{H2} = M_{H2}/(M_{H2}+M∗) as a function of galaxy mass in Figure 8. This quantity is often used as an observable tracer of the gas content of galaxies. Similar to the total cold-gas fraction, there is an anti-correlation between H2 and galaxy stellar mass, as well as redshift. High stellar mass

**Figure 7.** Cold gas fraction of galaxies (f_{gas} = M_{H2}/(M_{H2}+M∗)) as a function of stellar mass and redshift. The shaded regions show the log of the conditional probability distribution function P(f_{gas}|M∗), and the blue solid and dotted lines show the median fit and one σ deviation. The black solid and dashed lines show the mean fit and one σ deviation to the predictions of Popping, Somerville & Trager (2014).

**Figure 8.** Relative molecular content as a function of stellar mass for different redshift bins. The shaded region shows the log of the conditional probability distribution function P(M_{H2}/(M_{H2}+M∗)|M∗), and the blue solid and dotted lines show the median fit and one σ deviation. The black solid and dashed lines show the mean fit and 1 σ deviation to the predictions of Popping, Somerville & Trager (2014). Purple pentagons, circles, squares and diamonds are literature values from Daddi et al. (2010), Tacconi et al. (2010), Tacconi et al. (2013), and Saintonge et al. (2013), respectively.
galaxies have on average the lowest relative H₂ content, and \( f_{\text{H}_2} \) decreases with redshift at a fixed stellar mass. The trend in \( f_{\text{H}_2} \) with stellar mass is similar to that for total cold-gas fraction. We compare the results of our model with direct observations (through CO) of \( f_{\text{H}_2} \) in star-forming galaxies from Tacconi et al. (2010), Saintonge et al. (2013), and Tacconi et al. (2013). Although direct observations of \( f_{\text{H}_2} \) do not lie on top on the mean trend, they are in good agreement with the most massive and H₂-rich galaxies in our sample. As discussed when we described Figure 5, the difference between the mean trend and observations is driven by different selection criteria. Tacconi et al. (2013) developed a formalism to correct gas fractions for this selection effect and found gas fractions of \( \sim 30 \) per cent at \( z = 1 - 1.5 \) for galaxies with stellar masses \( \sim 10^{11} M_\odot \), in reasonable agreement with our inferred gas fractions.

We present the relative amount of atomic hydrogen in galaxies (\( f_{\text{HI}} = \frac{M_{\text{HI}}}{M_{\text{HI}} + M_*} \)) as a function of stellar mass for different redshift bins in Figure 9. Similar to the previous figures, \( f_{\text{HI}} \) decreases with stellar mass. Below stellar masses of \( \sim 10^9 M_\odot \) the H\(_1\) mass of galaxies exceeds the stellar

---

**Figure 9.** Relative atomic hydrogen content as a function of stellar mass for different redshift bins. The shaded region shows the log of the conditional probability distribution function \( P(\frac{M_{\text{HI}}}{M_{\text{HI}} + M_*} | M_*) \), and the blue solid and dotted lines show the median fit and one \( \sigma \) deviation. The black solid and dashed lines show the mean fit and 1 \( \sigma \) deviation to the predictions of Popping, Somerville & Trager (2014).

**Figure 10.** Molecular fraction (\( f_{\text{H}_2} = \frac{M_{\text{H}_2}}{M_{\text{gas}}} \)) of the cold gas as a function of stellar mass for different redshift bins. The shaded region shows the log of the conditional probability distribution function \( P(\frac{M_{\text{H}_2}}{M_{\text{gas}} + M_*} | M_*) \), and the blue solid and dotted lines show the median fit and one \( \sigma \) deviation.
mass, whereas at higher stellar mass the H I mass is less than the stellar mass. Interestingly, there does not seem to be a strong evolution in the trend between \( f_{\text{HI}} \) and stellar mass with time. A similar transition mass from H I to stellar mass dominated is seen for local galaxies (e.g., Cortese et al. 2011; Huang et al. 2012).

In Figure 10 we present the molecular fraction of the cold gas (\( f_{\text{H}_2} \equiv \frac{M_{\text{H}_2}}{M_{\text{gas}}} \)) as a function of stellar mass for different redshift bins. This is a good measure of the fraction of gas available for SF as a function of time. The relation between \( f_{\text{H}_2} \) and stellar mass is relatively flat at \( z > 2.5 \). We find an increasing trend between \( f_{\text{H}_2} \) increasing with stellar mass towards lower redshifts. We find that \( f_{\text{H}_2} \) increases with stellar mass up to a stellar mass of \( \sim 10^{10} \text{M}_\odot \) and decreases at higher stellar masses in our lowest redshift bins (0.5 < \( z < 1.0 \)). The average \( \text{H}_2 \) fraction of galaxies decreases with time at fixed stellar mass (only at \( M_\star > 10^{10} \text{M}_\odot \) do galaxies at \( 2.0 < z < 2.5 \) have higher \( f_{\text{H}_2} \) than at \( z > 2.5 \)). This result clearly shows that both the cold gas and \( \text{H}_2 \) reservoirs decrease with time, although not necessarily at the same rate. It is important to note that the relation between stellar mass and \( \text{H}_2 \) fraction has a large scatter, especially at low stellar masses and lower redshifts. There is no well defined drop in \( \text{H}_2 \) fraction at a characteristic stellar mass and/or time.

We show the mean trends of the previous four Figures again in Figure 11 with the aim of focusing on the evolution of these trends. We find the remarkable result that \( f_{\text{gas}}, \ f_{\text{HI}}, \ \text{and} \ f_{\text{H}_2} \) all decrease as a function of time, whereas \( f_{\text{HI}} \) remains nearly constant. Although the gas content of galaxies at fixed stellar mass decreases as a function of time, the changed partitioning of cold gas in H I and H 2 results in a constant fraction of H I in galaxies with fixed stellar mass. We discuss this further in Section 5.

The CANDELS results suggest a gradual evolution in the cold gas fraction and the relative molecular hydrogen content of galaxies at 0.5 < \( z < 3 \), independent of stellar mass.

### 3.3.1 Model comparison

As a comparison we included predictions from the semi-analytic model presented in Popping, Somerville & Trager (2014) in Figures 7, 8, and 9. We ran the models in the appropriate redshift bins and applied a CANDELS selection criteria to the model output (\( H_{\text{AB}} < 26 \)). We only selected disc-dominated galaxies (bulge-to-total ratio less than 0.4).

Although the results presented in this paper are merely model predictions, they are based on actual observables.
Gas evolution in CANDELS galaxies

Figure 13. Galaxy SFR as a function of stellar mass for different redshift bins. The colour map gives the molecular fraction of the cold gas.

rather than introducing uncertain recipes describing the physics acting on galaxies. A comparison between the results presented in this work and semi-analytic predictions can shed light on the successes and failures of theoretical models. We acknowledge that the results presented are effectively a different representation of the phase space described by stellar mass, SFR, and galaxy size. One could therefore also compare the observed values for these quantities to semi-analytic model predictions. Nevertheless, focusing on the gas masses of galaxies and potential discrepancies between the results presented in this work and semi-analytic model predictions may provide a more direct hint of the baryonic physics that need to be changed and/or included for models to reach better agreement with observations. Somerville & Davé (2014) showed that semi-analytic models and hydrodynamic models predict too little SF in galaxies at redshifts $z = 1$ and $z = 2$ (for a potential solution see Henriques et al. 2014; White, Somerville & Ferguson 2015). Our method has the potential to assess whether this is due to too low gas masses in general or too little $H_2$.

The semi-analytic model predictions are in good qualitative agreement with our inferred cold gas fractions at redshifts $z = 0.5$ to $z = 2.5$ (Figure 7). We predict up to 10 per cent more cold gas in galaxies with stellar masses larger than $10^{10} M_\odot$ than the semi-analytic model. At higher redshift the semi-analytic model predicts gas fractions higher than found in this work for galaxies with stellar masses larger than $10^{10} M_\odot$.

Semi-analytic model predictions are in good qualitative agreement with our inferred $H_2$ masses at redshifts $1 < z < 1.5$ (Figure 8). At lower redshifts the semi-analytic model predicts much less molecular hydrogen than the results presented in this paper, whereas the model predict on average 1.8 times less molecular hydrogen at higher redshifts ($f_{H2}$ is approximately 10 per cent less). In the highest-redshift bin the model overpredicts $f_{H2}$ compared to the inferred fractions at $M_\ast > 10^{10} M_\odot$, whereas it underpredicts the relative amount of $H_2$ in galaxies at lower stellar masses.

The Popping et al. semi-analytic model on average predicts higher values for $f_{HI}$ at stellar masses less than $10^{10} M_\odot$ than the results presented in this work. The model also finds that at redshifts $z = 3 - 1$ the amount of $H_1$ in galaxies at fixed stellar mass remains relatively constant. We will further discuss the implications of this comparison in the discussion.

3.4 Gas properties on the stellar mass–SFR diagram

In Figure 12 we show the cold gas fraction of galaxies on the stellar mass–SFR relation. We find that to first order, galaxy cold gas fractions are well parameterized by their stellar mass and SFR. It is important to realize that both the SFR and the stellar mass of a galaxy are key ingredients in our model that set a galaxy’s cold gas mass and its partitioning into atomic and molecular hydrogen. Galaxy gas fractions stay constant parallel to the relation between SFR and stellar mass, increasing towards higher SFR and decreasing with stellar mass. The upper envelope in the stellar mass–SFR diagram is populated by the most gas-rich objects at a given stellar mass. Although counterintuitive, galaxies with the highest SFRs do not necessarily have the highest gas fractions. The highest gas fractions are found in galaxies with low stellar masses and high SFRs. Galaxies with high stellar mass and low SFRs have the lowest gas fractions. At a fixed position in the stellar mass–SFR diagram galaxy cold gas fractions decrease with time.

We explore the $H_2$ fraction of galaxies in the stellar mass–SFR plane in Figure 13. Molecular gas fractions increase with increasing SFR. The most actively star-forming galaxies have highest molecular gas fractions, and the least-actively star-forming galaxies have the lowest fractions. Molecular fractions cannot be parameterized by a simple
combination of stellar mass and SFR as the total cold-gas fractions.

More information can be obtained by comparing Figures [12] and [13]. These figures clearly show that large cold-gas reservoirs do not necessarily lead to large molecular-gas reservoirs and active SF. This is especially evident for galaxies with low stellar mass (\(\sim 10^8 M_\odot\)) and SFR \(\sim 1 M_\odot\) yr\(^{-1}\) at \(z < 1.5\). These galaxies are dominated by atomic gas. Despite being rich in cold gas, only approximately 25 per cent of their cold gas is molecular and available to form stars. These objects were below the observation limit of the galaxies in [Popping et al. 2012]. The deep near-IR photometry of the CANDELS survey allows us to study these atomic-gas-dominated low-mass galaxies. Observations of local galaxies show a similar decrease in H\(_2\) fraction with decreasing stellar mass [Saintonge et al. 2011; Boselli et al. 2014; Bothwell et al. 2014], with on average even lower H\(_2\) fractions than the galaxies in our sample.

The most actively star forming galaxies (\(\sim 10^{11} M_\odot\) and SFR \(\sim 100 M_\odot\) yr\(^{-1}\)) at \(z < 2.5\) have relatively small cold gas reservoirs (\(f_{\text{gas}} < 0.5\)), but most of this cold gas is molecular. Galaxies with high stellar mass and low SFRs are nearly empty of cold gas, but the molecular fraction of this gas is approximately 0.5 and can account for some residual star-formation.

### 3.5 Gas properties on the stellar mass – size relation

We present the cold-gas and molecular fraction of galaxies on the stellar mass–size relation in Figures [14] and [15]. Within our model the scale radius of a galaxy sets the surface densities that control the molecular fraction and the total mass of cold gas in that galaxy. At fixed stellar mass the cold gas fractions of star-forming galaxies increase with increasing size. The molecular fraction of the cold gas, on the other hand, decreases with increasing size. For a fixed scale radius the cold-gas fraction and molecular fraction of a galaxy decrease with time.

The largest variations in molecular fractions are found in low-stellar-mass galaxies (\(M_* < 10^{10} M_\odot\)). At higher stellar masses we find differences in molecular fraction of approximately 25 per cent. Although less dramatic than for lower-mass galaxies, such variations are still significant.

### 3.6 Star-formation efficiencies

The star-formation efficiency (the ratio between SFR and total cold gas mass (H\(_1\) + H\(_2\)), i.e., SFE \(\equiv\) SFR/(\(M_\odot\) yr\(^{-1}\)) is a good measure of how efficiently galaxies turn cold gas into stars [8]. We show the SFE of galaxies on the stellar mass–SFR and stellar mass–size diagrams in Figures [16] and [17].

We find that galaxy SFEs increase with increasing SFR and decrease with time. The SFE of galaxies that populate the upper envelope in the stellar mass–SFR relation changes as a function of stellar mass. At high stellar masses, galaxies are more than twice as efficient in forming stars out of their total cold gas reservoirs (H\(_1\) + H\(_2\)) than at low stellar masses. This shows that the position of a galaxy on the stellar mass–SFR plane is being driven by the amount of cold gas available and by the ability of the gas to form molecules and stars [Saintonge et al. 2012; Genzel et al. 2014; Sar gent et al. 2014]. The group of galaxies with low SFRs at high stellar masses is more than twice as inefficient in forming stars than their counterparts with the same stellar mass that are actively forming stars. Overall, the SFE of galaxies decreases with time.

The SFE of galaxies decreases with increasing scale ra-

---

4 We note that the star-formation efficiency of galaxies is often defined as the ratio between SFR and molecular hydrogen mass H\(_2\) (i.e., SFE \(\equiv\) SFR/M\(_{H_2}\)). Our adopted definition of the ratio between SFR and total cold gas mass is slightly different and important for simulations that do not discriminate between H\(_1\) and H\(_2\).

3.7 Global evolution of cold gas content of galaxies

The evolution of $f_{\text{H}_2}^*$ with redshift has been studied in several different CO surveys and through dust continuum estimates (Geach et al. 2011; Tacconi et al. 2010; Daddi et al. 2010; Magdis et al. 2012; Tacconi et al. 2013; Saintonge et al. 2013; Bauermeister et al. 2013; Genzel et al. 2014; Scoville et al. 2014). These surveys suggest $f_{\text{H}_2}^*$ increases with increasing redshift up to $z \sim 2$ and flattens or even declines at higher redshifts (Saintonge et al. 2013).

We present the evolution in $f_{\text{H}_2}^*$ for galaxies with different selection criteria in stellar mass and SFR in Fig. 18 (top row). Our method allows us to infer the gas content for a large number of galaxies covering a wide range in physical properties (stellar masses, SFRs). This makes it ideal to investigate the effects that different selection criteria have on cold gas evolution trends inferred from direct observations of the CO emission line and the dust continuum of galaxies.
We find a decrease in the relative H$_2$ content of galaxies from $z \sim 3$ to $z \sim 1$. There is a minor increase in the relative H$_2$ content (and other fractions) from $z = 1.0$ to $z = 0.5$ when selecting galaxies with stellar masses larger than $10^9 M_\odot$. Above $z = 2.0$ the evolution of f$_{H_2}$ becomes less steep. This observed evolution is similar to the results presented in Sanz-Grande et al. (2013). The normalization and the shape of the evolution in f$_{H_2}$ depend on the selection criteria applied. We find the best match with the current direct observations when selecting only galaxies with SFR $> 30 M_\odot$ yr$^{-1}$ for galaxies with stellar masses log (M$_*$/M$_\odot$) $> 10.0$, similar to the selection limits of the observed samples. When loosening the selection criteria for SFR the normalization of f$_{H_2}$ decreases. These galaxies with low SFRs are currently typically not accounted for in direct surveys of the molecular content of galaxies through either CO or FIR sub-mm continuum studies. When including galaxies with lower stellar masses we find that not only the normalization in the evolution of f$_{H_2}$ increases, the slope of the decline in f$_{H_2}$ at $z \lesssim 2$ also becomes stronger. We find no changes in the evolution of f$_{H_2}$ when selecting galaxies with stellar masses more massive than $10^9$ solar masses and changing the SFR criteria.

The relative amount of atomic hydrogen in galaxies slightly decreases with time in galaxies with stellar masses larger than $10^9 M_\odot$ and remains constant in galaxies with stellar masses more massive than $10^{10} M_\odot$.

The mean molecular fraction f$_{H_2}$ of the cold gas in galaxies gradually decreases over the entire redshift range probed. This is in good agreement with the results presented in Figure 10 where we showed that the mean molecular fractions as a function of stellar mass decreases by approximately 25 per cent for the lowest mass galaxies from redshift 3 to 0.

4 MODEl ASSUMPTIONS AND APPLICABILITY TO THE CANDELS SAMPLE

The presented approach is based on several assumptions that may not always hold. In this section we discuss the main assumptions and how they affect our inferred gas masses.

We converted all the sizes to a common restframe wavelength of 5000 Å. Originally they were based on H-band photometry. Across the $z = 0.5$–3 redshift range the H-band photometry spans a restframe size from the B band to the I band. Inferred gas masses based on the 5000 Å restframe morphology are slightly higher than based on the original H-band morphology. When adopting the 5000 Å restframe morphology, less than 5% of the galaxy sample is more than 10% more gas rich than when adopting the H-band morphology. Only a handful of objects is more than 20% more gas rich when adopting a 5000 Å morphology, rather than the H-band morphology.

A key assumption in our method is an exponential distribution of stars and gas in the galaxy discs. SF takes place in molecular clouds (local clumps in the disc not following an exponential distribution) which could lead to a local underestimation of the cold gas surface density. In this work we are averaging over ~kpc scales and at our redshifts of interest and at these scales the exponential disc model is a good approximation to the stellar distribution of star-forming galaxies on galactic scales (Wuyts et al. 2011). Furthermore, analyses of local galaxies have revealed an exponential distribution of the cold gas in star-forming galaxies (Leroy et al. 2008; Bigiel & Blitz 2012; Kravtsov 2013; Wang et al. 2014).

Our model assumes a constant ratio between the gas and stellar disc scale lengths ($\chi_{gas} = 1.7$), based on fits to the galaxy disc profiles in Leroy et al. (2008). This number is in good agreement with typical ratios of 1.5–2.0 between H1 and optical disk sizes (Verheijen & Sancisi 2001; Kravtsov 2013) finds a $\chi_{gas} = 2.6$, when normalizing gas profiles to a radius $r_n$ obtained using abundance matching arguments.

Figure 17. Galaxy scale radius as a function of stellar mass for different redshift bins. The colour map gives the star-formation efficiency (SFE $\equiv$ SFR/M$_{gas}$) of the galaxies.
Gas evolution in CANDELS galaxies

Figure 18. Redshift evolution of the relative H$_2$ content $f_{H_2}$ (top row), gas fraction (second row), relative H1 content (third row), and molecular hydrogen fraction (bottom row) for galaxies with stellar masses in the range $M_*>10^9M_\odot$ (left panels), $M_*>10^{10}M_\odot$ (right panels), and SFR larger than 0 (red), 5 (green), 10 (orange), and 30 (blue) $M_\odot$ yr$^{-1}$. Different markers represent the following datasets: upwards pointing triangles: galaxies from the THINGS survey (Levay et al. 2008) at $z=0$, pentagons: galaxies from the COLD GASS survey (Saintonge et al. 2011) at $z=0$, squares: galaxies from Bauermeister et al. (2013) at $z=0.4$, stars: galaxies from Genzel et al. (2011) at $z=0.4$, circles: galaxies from the PHIBBS survey (Tacconi et al. 2013) at $z=1.2$ and $z=2.2$, downwards pointing triangles: galaxies at $z=1.2$ and $z=2.2$ from Tacconi et al. (2010), diamonds: galaxies at $z=2.2$ from Saintonge et al. (2013). Error bars show the 80 percent confidence interval for each observational sample at the given redshift bin.

Furthermore, the value for $\chi_{gas}$ may vary as a function of redshift or galaxy properties. Varying $\chi_{gas}$ results in negligible differences in inferred cold gas and H$_2$ mass as long as $\chi_{gas}>1$. Decreasing $\chi_{gas}$ to values less than one leads to more significant differences in the inferred gas masses. When adopting the extreme case of $\chi_{gas}=0.5$ we find that the inferred gas and molecular masses are lowered by 0.25 and 0.1 dex, respectively. Observations of the sizes of the CO discs at $z=1.2$ and $z=2.2$ (supposedly tracing the molecular hydrogen) do not support a scale length ratio of $\chi_{gas}>1$ (e.g. Tacconi et al. 2010 2013). Berry et al. (2014) found that in semi-analytic models H1 discs have to be more extended than the stars in order to reproduce Damped Lyman-alpha properties (Schaye 2001).

A key ingredient in our model is the partitioning of cold gas into a molecular and atomic component using a pressure-based recipe presented in Blitz & Rosolowsky (2006). This recipe was calibrated based on observations in local galaxies (Blitz & Rosolowsky 2006 Leroy et al. 2008) and has not yet been constrained at our redshifts of interest. An increased UV background or lower gas metallicities could suppress the formation of molecules on dust grains and the ability of the molecular hydrogen to shield. Under these conditions our model would require a larger inferred cold gas reservoir to support the observed SFRs. We anticipate that future high-resolution observations with ALMA and SKA will be able to assess the validity of these locally calibrated relations at high redshifts. An alternative approach would be to use a molecular hydrogen prescription that is also a function of gas phase metallicity (e.g., Krumholz, McKee & Tumlinson 2009 Gnedin & Kravtsov 2011). Similarly to the pressure based algorithm, these prescriptions have also only been tested against local observations (e.g. Fumagalli, Krumholz & Hunt 2010). A significant downside of applying this approach is that gas-phase metallicities are only available for a limited number of galaxies at our redshifts of interest. A different approach could be to use the fundamental metallicity relation (Mannucci et al. 2009) to estimate the gas-phase metallicity of galaxies as a function of their SFR and stellar mass. We opted not to use this approach, as this will introduce an additional empirical step and source of uncertainty. Moreover, the calibration of gas phase metallicity measurements is highly uncertain.

We assume an adapted version of the SF relation presented in Bigiel et al. (2008) to allow for an increased star formation efficiency in high-surface-density environments. When not accounting for the increased star-formation efficiency (i.e. $N_{SF}=0$), the presented method predicts larger values for the gas content of galaxies with SFR/(2$\pi r_s^2$)$\approx$1$M_\odot$yr$^{-1}$kpc$^{-2}$ by roughly 10 percent and SFR/(2$\pi r_s^2$)$\approx$10$M_\odot$yr$^{-1}$kpc$^{-2}$ by roughly 75 percent (less than 1 percent of our sample has a SFR surface density larger than SFR/(2$\pi r_s^2$)$\approx$10$M_\odot$yr$^{-1}$kpc$^{-2}$).

To estimate the mid-plane pressure on the disc we adopt the prescription presented in Elmegreen (1989). We estimate the ratio between the gas and stellar vertical velocity dispersion following Pu et al. (2010), based on empirical scalings for nearby disc galaxies. Observations suggest that star-forming galaxies at $z=2$ are “puffy” with high velocity dispersions (Förster Schreiber et al. 2009). Depending on the actual distributions of the giant molecular clouds and star-forming clumps, this may change the shielding properties of the molecular hydrogen.

An additional source of uncertainty lies in the conversion from CO emission to H$_2$ mass (see Bolatto, Wolfe & Leroy 2013 for a review) or the conversion from sub-mm dust continuum to gas mass. Our method is calibrated on H$_2$ masses that rely on the aforementioned conversions. Our method therefore includes these uncertainties.

In (e.g., Popping et al. 2012, Figure 3) we showed that propagating the uncertainty in the input parameters (stellar mass, SFR, and size), the typical systematic uncertainty in inferred gas masses is approximately 0.3 dex. Many of the uncertainties cannot be well quantified. Combining all the concerns discussed above as well as the concerns discussed in Popping et al. (2012 Section 3.3), and taking the errors in the input parameters into account, we estimate an uncertainty in the inferred gas masses for our method is approximately 0.7 dex.
5 DISCUSSION

5.1 Galaxy gas fractions

The gas fraction of a galaxy is set by the competition between the inflow, outflow, and consumption of cold gas in the galaxy (Bouché et al. 2010 Davé, Finlator & Oppenheimer 2011 Dekel & Mandelker 2014). The cosmic SFR peaks at \( z \sim 2 \) (Hopkins & Beacom 2006 Madau & Dickinson 2014), and analytic calculations and cosmological hydrodynamical simulations predict large gas accretion rates onto galaxies at this epoch (Birnboim & Dekel 2003 Keres et al. 2005 2009 Dekel & Birnboim 2006 Dekel et al. 2009). Our indirect gas measures provide an ideal sample to constrain which of the aforementioned processes dominate this competition at different cosmic times. We find that gas fractions decrease most rapidly at \( z < 1.5 \), although a gradual decrease is present at all redshifts studied in this sample. These results suggest that the accretion of gas onto galaxies cannot keep up with the consumption and/or outflow of gas, especially at redshifts \( z < 2 \) (see also Popping et al. 2012). These results are in good qualitative agreement with predictions from semi-analytic and semi-empirical models (e.g., Obreschkow & Rawlings 2009 Lagos et al. 2011 Fu et al. 2012 Popping, Somerville & Trager 2014 Popping, Behroozi & Peeples 2015). Besides the relative gas content, the molecular fraction of the cold gas also decreases with time, most rapidly at \( z < 2 \) (Saintonge et al. 2013).

The characteristic density of the cold gas decreases (Popping et al. 2014), allowing less gas to self-shield and become molecular. This indicates that the physical process that suppresses star-formation with time is at least two-fold: galaxies run out of gas as well as molecules, but not necessarily at the same rate. For the most massive galaxies in our sample this two-fold process is already taking place at \( z \sim 3 \), well before the peak in cosmic SFR and before the accretion of cold gas onto galaxies slows due to the increasing dominance of dark energy driven expansion. This is an important constraint for models of galaxy formation that include H\(_2\)-based star-formation recipes.

The rapid decrease in cold gas fractions below \( z < 1.5 \) is supported by direct observations of the CO emission in galaxies (Figure 18 Tacconi et al. 2013 Saintonge et al. 2013). These observations indicate that the relative H\(_2\) content of galaxies remains flat above redshifts of \( z \sim 2 \) and gradually decreases at lower redshifts. The slope and normalization of this trend is in part set by the selection criteria. Depending on the selection criteria in stellar mass and SFR chosen, the evolution of \( f_{\text{gas}} \) at redshifts \( z > 2 \) can change.

Popping et al. (2012) found for a sample of galaxies taken from COSMOS at redshifts \( 0.5 < z < 2 \) that the cold gas fraction of galaxies with stellar masses of \( \sim 10^{10.5} M_\odot \) evolves from \( f_{\text{gas}} \sim 1 \) at \( 1.75 < z < 2 \) to \( f_{\text{gas}} \sim 0.2 \) at \( 0.5 < z < 0.75 \). The authors found that less-massive galaxies showed hardly any variation in their gas fractions. This difference suggested that massive galaxies become gas-poor earlier and quicker than less massive galaxies; this behaviour was characterized as downsizing in gas content. Furthermore, the authors found a characteristic stellar mass below which the gas fraction of galaxies rapidly drops. This characteristic mass decreased towards lower redshifts. We find a similar characteristic stellar mass at redshift \( 2.5 < z < 3 \), but the drop in the relation between cold gas mass and stellar mass disappears towards lower redshifts. Also, there is no strong difference in the rate at which the highest mass galaxies run out of cold gas compared to the least massive galaxies in our sample (see Figure 11). We remind the reader that the CANDELS survey allows us to study much fainter objects and is not biased towards the most star-forming objects. We ascribe the conclusion reached in Popping et al. (2012) to the selection of only the most actively star-forming, and therefore most gas rich, galaxies at stellar masses less than \( 10^{8.5} M_\odot \). Our results suggests a gradual evolution in the cold gas fraction and the relative molecular hydrogen content of galaxies at \( 0.5 < z < 3 \), independent of stellar mass.

5.2 Extended parameter space and selection effects

With the technique used in this work we can easily infer the cold gas masses for large samples of galaxies, covering a wide range in stellar mass, SFR, and redshift. As discussed above, this allows us to evaluate the impact of selection effects on smaller surveys of directly measured gas masses and to extend observed relations to stellar mass, SFR, and redshift regimes where gas measure are hard to obtain directly.

CO observations of actively star-forming galaxies have revealed a linear relation between \( H_2 \) mass and stellar mass (e.g. Saintonge et al. 2013 Tacconi et al. 2013). Our results suggest that this relation was already in place at \( z = 3 \), when the Universe was less than 3 Gyr old and extends down to stellar masses of at least \( 10^8 M_\odot \). A similar relation (although less well defined) is found for the total cold gas mass and H I mass. The trend between stellar mass and H I mass has larger scatter than the trend between stellar mass and cold gas mass and \( H_2 \) mass. Even though the uncertainties in the gas masses are significant, these extended scaling relations suggest that the balance between the consumption and in- and outflow of gas in galaxies is already at place for galaxies with low stellar masses.

In Figure 15 we explored the direct effect of changing selection criteria on the evolution of gas fractions in galaxies. We found no qualitative difference between different selection criteria. The fraction of gas, H I, and \( H_2 \) in galaxies decreases gradually from \( z = 3 \) to \( z = 0.5 \). The absolute values of the gas fractions change by a factor of a few when changing the selection criteria. We find that for a sample of galaxies with stellar masses more massive than \( 10^8 M_\odot \) the inferred cold gas, H I, and \( H_2 \) fractions of galaxies remain nearly identical when galaxies with a reasonable amount of SF are selected (SFRs of a few solar masses per year). Future surveys with a stellar mass limit of \( 10^8 M_\odot \) should be able to robustly constrain the evolution of the gas content of galaxies contributing most to the stellar mass budget and stellar growth in our Universe.

We found good agreement between direct observations of the \( H_2 \) mass of galaxies and our inferred \( H_2 \) masses for the galaxies with the highest SFR in our sample (with SFR > \( 20 - 30 M_\odot \) yr\(^{-1}\)). Our results indicate that at the stellar masses probed by direct surveys, there is also a substantial population of galaxies with \( H_2 \) masses less massive than \( 10^{10} M_\odot \). This group of galaxies should be accounted for when trying to make more generalized statements, especially when focusing on galaxies with large stellar masses.
5.3 A constant relation between H I mass and stellar mass

We found hardly any evolution in the relation between H I mass and stellar mass, whereas the relation between cold gas mass and H2 mass with stellar mass does evolve. Popping, Behroozi & Peeples (2015) found a similar result when coupling an abundance matching model with the semi-empirical approach to infer gas masses adopted in this work. Semi-analytic, semi-empirical, and hydrodynamic models have also found a constant relation between H I mass and stellar mass remains constant with time (for galaxies with stellar masses larger than 10^9 M⊙), just as the H I mass function out to z = 2 (Dutton, van den Bosch & Dekel 2010; Lagos et al. 2011; Fu et al. 2012; Davé et al. 2013; Popping, Somerville & Trager 2014; Popping, Behroozi & Peeples 2015).

Although already predicted by different models, this is the first time a model used actual observations as input to find a constant H I-to-stellar mass ratio. The relatively weak evolution in H I mass is driven by an apparent self-regulation that naturally arises in galaxies. As gas is consumed over time and galaxies grow as a function of stellar mass, the cold gas surface density decreases which naturally causes the H I fraction of the cold gas to increase. Although this process may prevent a rapid drop in the H I reservoirs of galaxies, by no means does this process imply that the H I mass at a fixed stellar mass should remain constant. There is a fine balance between the amount of cold gas being consumed, heated and/or expelled, and the partitioning of the remaining gas into an atomic and molecular component that sets the constant H I mass.

We are aware that this result should be placed within the context of the model framework adopted in this (and other) work. If the adopted recipes for SF and the partitioning of cold gas are not valid for galaxies at z > 0 this could also dramatically change our conclusions. We therefore look forward to surveys with the SKA pathfinders probing the H I mass of galaxies out to at least z = 1. If indeed the H I-to-stellar mass fraction of galaxies remains constant, it should be feasible to observe the H I mass of M*, galaxies at z = 1–1.5 (Carilli & Rawlings 2004).

5.4 Comparing predictions by a theoretical model to inferred gas masses

Semi-analytic models of galaxy formation start from a cosmological framework for structure formation, and include physical recipes to describe the baryonic physics acting on galaxies (such as the cooling and accretion of gas, star formation, and outflows). In this work we started from observed quantities and converted them into other quantities using empirical scaling laws. Although many of the ingredients are the same for the two approaches, their different nature makes them very complementary. Any tension between predictions from semi-analytic models and this work can shed light on the successes and failures of theoretical models.

We find that the Popping, Somerville & Trager (2014) semi-analytic model predicts three times less molecular hydrogen than our inferred gas masses suggest at redshifts 0.5 < z < 1.0. The semi-analytic model predicts on average about 2 times less molecular hydrogen at redshifts 1.0 < z < 2.5. The same holds for galaxies at redshifts 2.5 < z < 3 with stellar masses less than 10^{10} M⊙. Similarly, we find that the semi-analytic model predicts less cold gas in galaxies at redshifts 0.5 < z < 3 than our inferred gas masses suggest.

Although the difference between semi-analytic model predictions and our inferred gas masses is not huge (and well within the uncertainty range of the method used in this work), it fits well within a broader picture where theoretical models predict too little SF for galaxies at redshifts 1 < z < 3 (Somerville & Davé 2014). If the molecular hydrogen masses of modeled galaxies are too low for their stellar mass, the SFRs of those galaxies will be too low as well when a molecular gas based star-formation recipe is used.

Popping, Behroozi & Peeples (2015) extended the sub-halo abundance matching approach with recipes to infer cold gas masses. They found that the same semi-analytic model as used in this work predicts less molecular hydrogen and cold gas at redshifts 1 < z < 3 than their extended sub-halo abundance approach suggests (see also Somerville & Davé 2014; White, Somerville & Ferguson 2015). A comparison with different semi-analytic models (Obreschkow & Rawlings 2009; Lagos et al. 2011) yielded the same results, making this a more general problem.

5.5 What drives the star-formation efficiency of galaxies

We have shown that, when using our model, the molecular fraction of the cold gas is a very important quantity that cannot be neglected. Despite large total cold gas masses, low molecular fractions can suppress the formation of stars and result in low SFEs. Indeed the SFEs of galaxies on the relation between SFR and stellar mass increases with stellar mass (Saintonge et al. 2013). However, our model implies that the physical state of the cold gas varies strongly as a function of stellar mass along the stellar mass–SFR relation.

To understand the origin of the varying molecular fractions and SFE, we have to look at the galaxy properties that enter our model. Within our model the cold-gas and molecular-gas content of a galaxy is set by a combination of its SFR, stellar mass, and size. Most important is the combination of SFR and scale radius, which sets the SFR surface density distribution of the galaxy. Within our model, low SFR surface densities result in low H2 surface densities. However, to ensure the pressure of the gaseous disc is high enough for the cold gas to collapse and form molecules, low H2 surface densities require relatively small cold-gas surface densities. This argument can also be reversed: an increase in the scale radius of the gaseous disc lowers the surface density of the cold gas, naturally causing less H2 to self-shield and transform into stars. We see this in the galaxies with low stellar masses and large discs in our sample. These are galaxies with the highest gas fractions, but their molecular fractions and star-formation efficiencies are very low.

An increase in galaxy scale radius also has a significant effect on the SFE of galaxies with high stellar masses.
For $M_\star > 10^{10} M_\odot$, at fixed stellar mass galaxies with compact discs have higher SFEs (and molecular fractions) than galaxies with more extended discs. The lower surface densities allow for a higher shielding rate of the molecular hydrogen. At fixed stellar mass the SFE of galaxies also increases with increasing SFR. The change in SFE cannot account for differences in SFR of a few orders of magnitude, but it can lower the SFR by a factor of a few. To first order it is the absolute amount of cold gas that largely controls the gas density and SFR of a galaxy. The distribution of gas into an extended disc can act as a secondary mechanism to suppress the formation of molecules and lower a galaxy’s SFR.

In reality the formation of molecules does not solely depend on the surface density or midplane pressure of cold gas. Dust grains and metals are the primary catalysts and coolants of H2 formation. Dust grains also shield the molecular hydrogen from H2 dissociation by UV photons and photo-electric heating. The metallicity of the ISM is therefore an important extra component that controls the formation of molecules, especially in low-density environments. In addition to low densities, a low-metallicity environment therefore stimulates the build-up of large atomic gas reservoirs, preventing the cold gas from condensing and forming stars (Krumholz & Dekel 2012b, Berry et al. 2014, Popping, Somerville & Trager 2014, Somerville, Popping & Trager 2015). We have not included this effect in our model, but it would strengthen the role that low surface densities and the partitioning of cold gas into HI and H2 plays in the formation of stars. Furthermore, we have not discussed the destruction of molecular hydrogen by radiation from an AGN.

There is a large population of low-stellar-mass galaxies that are dominated by atomic gas. Only a minor fraction of their total gas content is molecular and can form stars.

The inferred SFE of galaxies increases along the relation between SFR and stellar mass. Although part of the same trend, the most-massive galaxies in our sample have SFEs more than twice as high as lower-mass galaxies. At fixed stellar mass the SFE and molecular fraction of the cold gas increase with galaxy compactness.

The adopted approach can be tremendously helpful in understanding the impact of selection biases for much smaller samples of directly observed gas masses, as well as extending scaling relation between gas mass and other galaxy properties to ranges and redshift difficult to reach through direct observations.

### ACKNOWLEDGMENTS

We thank the referee for a thorough report and very constructive comments that have improved the paper. GP thanks Romee Davé, Marco Spaans, and the galaxy group at the Kapteyn Institute in Groningen for stimulating input for this paper. This work is based on observations taken by the CANDELS Multi-Cycle Treasury Program with the NASA/ESA HST, which is operated by the Association of Universities for Research in Astronomy, Inc., under NASA contract NAS5-26555. GP acknowledges NOVA (Nederlandse Onderzoekschool voor Astronomie) for funding.
