Menière’s disease is a chronic, stressful disease with disabling symptoms such as (fluctuating) hearing loss, tinnitus and spontaneous vertigo attacks. The exact pathogenesis remains unknown, but the endolymphatic hydrops is the most commonly used pathophysiologic substrate (Merchant et al, 1995). Hydrops is supposed to be caused by a congenital or acquired reduction of endolymph absorption and a temporarily increased production of endolymph (Dunnebier et al, 1997). Its unpredictable character makes it a stressful disease.

Menière’s disease is amongst the conditions in which psychological factors are often emphasized. The early literature on psychological considerations in Menière’s disease focused on the psychosomatic causes and somatopsychic effects of the disease (Crary & Wexler, 1977; Hinchcliffe, 1967). Neither the psychosomatic or somatopsychic theory does seem to be the sole clarification for the development of Menière’s disease. Most of the studies are methodologically weak and provide no definitive support for the claims made (Van Cruissen et al, 2003).

Earlier studies have shown that Menière patients experience more anxiety, depression and phobia (Coker et al, 1989; Martin et al, 1991; Takahashi et al, 2001), while others did not (Savastano et al, 1996). It was also shown that Menière patients experience the same level of anxiety, depression and somatic complaints compared to patients with only vertigo (Monzani et al, 2001). In the field of personality characteristics, previous studies have described Menière patients as obsessive-compulsive persons, perfectionists and neurotics, who are supposed to be more vulnerable and have more stress exposure (Groen, 1983; Savastano et al, 1996; Stephens, 1975). On the other hand, other researchers classified the personality of Menière patients in the normal range (Sawada et al, 1997). A time-series analysis of stress and vertigo expression did not support the role of stress as a precursor of symptoms in Menière’s disease (Andersson et al, 1997). On the contrary, Söderman et al did find that emotional stress increased the risk of getting a vertigo attack (Söderman et al, 2004).

The former studies evaluated specific aspects of the psychological process. More likely, the disease is characterized by a continuous interaction of many psychological, physical, and environmental factors: symptoms of the disease worsen the emotional state, which in turn impairs the (perception of) symptoms. To our knowledge, all these factors have never been evaluated simultaneously in one study. To outline the psychological process...
in Menière’s disease, a general model of stress with stressors (physical and psychological disturbances), appraisal (coping and personality), and stress responses (psychological, physical and behavioural) is presented (Figure 1). All elements have their specific place and interrelate in this model. Whether the disease or the psychological condition presents first, remains unresolved and is probably irrelevant. More important is to know how the emotional and physical factors interact, and why one patient develops more frequent and severe problems after getting Menière’s disease than others.

Information about this psychological process and its factors might give us better insight into which Menière patients are most at risk, and in what way psychological support needs to be intensified. In this study, each factor in the model is qualified and quantified by means of validated, standardized measures containing the appropriate psychometric properties. Several self-report questionnaires were selected to assess daily stressors, coping, personality, physical and mental health, and quality of life.

We hypothesized that Menière patients have more daily stressors, cope with stressors less adequately, report more psychological symptoms, and have a worse quality of life than healthy reference groups. Moreover, we explore personality traits that make Menière patients more vulnerable for stressors.

**Patients and Methods**

**Study population**

Every week one patient suspected of Menière’s disease is admitted to our Otorhinolaryngology ward for three consecutive days to confirm the diagnosis of Menière’s disease and to exclude other audiovestibular diseases, using various tests. The diagnostic work-up includes standard ear, nose and throat-examination, several audiomeric and vestibular tests, MRI-scanning of the cerebellopontine angle, laboratory tests, and evaluation of symptoms using standardized questionnaires. Two weeks prior to admission all patients stopped their antivertiginous medication, including anxiolytics. Patients were considered to be suffering from Menière’s disease if they had a history of at least two vertigo attacks lasting longer than 20 minutes, tinnitus, and sensorineural hearing loss of at least 60 dB summed from the three worst octaves in the same ear, while other pathology was excluded. Aural fullness was not a requirement of the diagnosis, but could be present as well.

From January 2002 to January 2005, 132 consecutive patients with audiovestibular symptoms were admitted for clinical assessment. We diagnosed 111 patients with Menière’s disease and 21 individuals (16%) with other pathology, after evaluation of all the test results. This other pathology included acoustic neuroma, otosclerosis, neuritis vestibularis, ototoxicity, benign paroxysmal positional dysfunction, migraine, hereditary hearing loss, and partial epilepsy. Those patients with other audiovestibular diseases were considered as a control group. One Menière patient could not participate in the psychological assessment because of language problems. Of the 110 Menière patients, 81 were unilaterally (74%), and 29 were bilaterally (26%) affected. The study population consisted of 67 male (61%) and 43 female (39%) patients with a mean age of 52.9 ± 12.1 years, respectively. The male Menière patients had a total disease time of 8.3 ± 7.0 years, compared to the female group 8.0 ± 6.0 years. In this matching two outliers of the male group were excluded. They had a disease time of 36 and 56 years due to other ear problems. When they were included, the male total disease time was 9.4 ± 9.6 years. The total disease time was not significantly different for gender with or without the outliers.

A similar proportion of men (31/67; 46%) and women (23/43; 54%) had another chronic disease. The extended Fletcher index for the male and female group was respectively 53 ± 20.3 dB, and 49 ± 19.9 dB. Male and female patients rated their hearing loss, tinnitus and vertigo of the past three months, and the last week comparable, and they had a similar frequency of vertigo attacks lasting longer than 20 minutes in the past three months. The female patients had a significantly lower alcohol intake (p < 0.001, Chi square test). The education level was comparable for both genders.

---

**Figure 1.** Multi-factor model of Menière’s disease.
Psychological assessment
During the clinical admission the psychological evaluation of Meniere patients was performed using the following questionnaires:

1. The Daily Hassles List (APL) quantifies the frequency and intensity of problems in different circumstances (Vingerhoets & Van Tilburg, 1994). 112 situations are given, and have to be answered as to whether they had occurred in the past two months. If a positive reaction was given, it also had to be scored as to whether it was ‘not a problem at all (0)’, ‘not so bad (1)’, ‘bad (2)’ or ‘very bad (3)’. A higher score implies more daily hassles.

2. Coping was assessed with the Coping Inventory for Stressful Situations (CISS, Endler & Parker, 1990). 48 strategies of coping with stressful situations are mentioned and have to be answered from ‘not at all (1)’ to ‘very strongly (5)’. The CISS has three dimensions: task, emotion and avoidance oriented coping. The CISS has been translated and validated for the Dutch situation (De Ridder et al, 2004).

3. The NEO Five Factor Inventory (NEO-FFI, McCrae & Costa Jr., 1989) measures five personality domains: neuroticism, extraversion, openness to experience, altruism, and conscientiousness. 60 statements have to be answered on a five-point scale ranging from ‘strongly disagree’ to ‘strongly agree’. Higher scores specify that the specific trait is more pronounced. The NEO-FFI has been translated into Dutch and validated for the Dutch cultural situation (Hoekstra et al, 1996).

4. The Symptoms Checklist (SCL-90) is a multidimensional self-report questionnaire measuring physical and psychological complaints on a scale from one to five (Arindell & Ettema, 1986; Derogatis, 1977). It encompasses 90 items containing eight dimensions: anxiety, agoraphobia, depression, somatic complaints, obsessive-compulsive behaviour, interpersonal sensitivity (personal inadequacy and inferiority), hostility, and insomnia. The total score is called psychoneuroticism, which is a measure for general level of psychological and physical dysfunction. Higher scores indicate more psychological or physical problems.

5. The General Health Questionnaire (GHQ-12) is designed to screen for minor psychiatric disorders in the general population (Koeter & Ormel, 1989), 12 items are scored as to whether the situation was ‘better (0)’, ‘the same (0)’, ‘worse (1)’ or ‘much worse (1)’ as usual, with higher scores corresponding with a worse mental health (Goldberg & Hillier, 1979).

6. The 36-item Medical Outcome Short Form Health Survey (SF-36) evaluates well-being and functional status (quality of life). It contains the following dimensions: physical, mental and social functioning, role limitations due to physical or emotional problems, general health perception, bodily pain, and vitality. Each dimension has several items with different scales; a lower score represents worse functioning in that specific dimension (Aaronson et al, 1998).

The Daily Hassles List is a free translation of the APL (Alledaagse Problemen Lijst), which is a standardized and validated Dutch questionnaire. The other five tests are internationally standardized and validated tests, which have been translated into Dutch and validated for the Dutch cultural situation. The normative values of all tests match the Meniere cohort for age and are given for gender.

Duration and subjective severity of symptoms were scored using a self-report questionnaire. The duration time of Meniere symptoms (hearing loss, tinnitus and vertigo) was defined as the time between the first appearance of the symptom and the admission date. We defined the total disease time as the duration of the first presenting symptom. The duration of disease in those with bilateral disease was confined to the first affected ear. The subjective severity of the symptoms was assessed as perceived in the last three months. Hearing loss could be characterized as ‘unchanged’, ‘improved’, ‘worse’ or ‘fluctuating’; tinnitus, aural fullness, and vertigo as ‘none’, ‘mild’, ‘moderate’ or ‘severe’. The patients also had to score whether they had experienced vertigo attacks lasting more than 20 minutes in the past three months.

Furthermore, the symptoms of hearing loss, tinnitus, aural pressure, and vertigo had to be rated by the patients as ‘none’, ‘mild’, ‘moderate’ and ‘severe’ (1—4) as experienced in the past week. The total severity symptom score is a summation of these four separate scores (variance 4—16). The median total severity symptom score for the 110 patients was 10 and served as the cutoff point for creating the low (LSG) and high severity symptom group (HSG).

The presence of another chronic disease besides Meniere’s disease, alcohol and nicotine usage, and education level had to be noted as well. The hearing loss was defined as the extended Fletcher index over five pure-tone audiogram frequencies (250–4000 Hz).

Informed consent was obtained from all participants, and the study was approved by the medical ethics committee of our hospital.

Statistics
Data are given in mean ± standard deviation (SD). Statistical analyses were performed using the Student’s t-test, Chi-square and Mann-Whitney-test. Two-tailed p-values were used for all tests. Pearson product-moment correlation coefficients were used to examine relationships between variables. If appropriate, we made Bonferroni corrections for multiple comparisons. For each test we set the alpha level at 0.05 divided by the number of comparisons. For instance, for 10 comparisons: p = 0.05/10 = 0.005.

Results
Published normative data for all the questionnaires are derived from their respective manuals or papers (see methods section) and are given for gender. The results of the six questionnaires are presented in Tables 1 and 2. Some questionnaire test results had too many missing values and were therefore not used in the analysis. The main results are outlined below.

The Meniere patients, male and female, experienced more daily hassles compared to the normative values (Table 1). Also, they were less task-oriented in their way of coping with stressful situations. Moreover, the male patients were also less emotion and avoidant-oriented in their coping (Table 1). The personality test (NEO-FFI) showed that the Meniere patients had no...
The SCL-90 results illustrated that the Menière patients experienced more psychological and physical problems (Table 2). A GHQ-12 score of more than one indicates psychopathology (Table 2). In that case, 63% of the Menière patients showed psychopathology. More specific, 71% of the female and 58% of the male Menière patients revealed psychopathology. According to the SF-36 scores (quality of life), the Menière patients had more limitations due to their restricted physical functioning. They had a worse general health perception and poorer social functioning, and more bodily pain (SF-36). They were also less vital (SF-36). Both groups did not differ in their psychometric results for coping strategies (CISS), personality traits (NEO-FFI), mental health (GHQ-12) and psychopathology (SCL-90).

The psychometric results of the 110 Menière patients and the results of the patients with other audiovestibular diseases (control group, n = 21) were compared. This showed no significant difference in any of the psychological test results (Mann-Whitney test). The statistical comparison between these two groups is underpowered to detect differences in the psychological tests, because of the small size of the control group.

Both groups of patients with low and high severity symptom scores (LSG and HSG) were equally affected by the presence of other chronic diseases and had the same total disease time. The HSG experienced significantly more psychopathology (SCL-90) and a worse quality of life (SF-36) (Table 4). No differences in

daily stressors, coping or personality were found between the patients with mild and severe symptoms.

This study also showed some correlations between different psychological parameters, using Pearson product-moment correlation coefficients. Emotion oriented coping strategy use was positively correlated with neuroticism ($r = 0.68$), and negatively correlated with conscientiousness ($r = -0.21$). Also, emotion focused coping was correlated with psychoneuroticism ($r = 0.49$, SCL-90), general health ($r = -0.30$, SF-36) and mental health ($r = 0.35$, GHQ-12). Task oriented coping was positively correlated with extraversion ($r = 0.32$). The total severity symptom score was significantly correlated to neuroticism ($r = 0.27$, NEO-FFI), psychoneuroticism ($r = 0.39$, SCL-90), general health ($r = -0.29$, SF-36) and mental health ($r = 0.31$, GHQ-12).

**Discussion**

This study shows that Menière patients had a deviant psychological profile compared to published normed values. Menière patients experienced more daily stressors and used certain coping strategies less often. There was also more psychopathology and a worse quality of life in Menière patients. No abnormalities in personality were found.

To our knowledge no analysis has been carried out which evaluated all these separate factors in one study. The psychological test results seem comparable to other studies. The psychopathology (e.g. anxiety and depression) in Menière patients was also found by other researchers (Coker et al, 1989; Martin et al, 1991; Takahashi et al, 2001). The obsessive-compulsive and neurotic personality found by others, could not be confirmed in our study (Savastano et al, 1996; Stephens, 1975). On the contrary, Sawada et al did classify the personality structure in the normal range (Sawada et al, 1997). It remains difficult to compare these studies due to the use of different types of tests.

It has also been shown that Menière patients experience a bad quality of life, and vertigo seems to be the most influencing factor on the major implications of this disease on their daily lives (Cohen et al, 1995; Hagnebo et al, 1997; Söderman et al, 2002). A strong sense of coherence (ability to cope with stressful situations) appears to be an important predictor of Menière patients' perception of symptoms and quality of life, according to Söderman et al, 2001. They suggest that the quality of life or perception of the disease is also a result of the patient's ability to cope with difficult life situations. This is also suggested in our study with the positive correlation between emotion oriented

**Figure 2.** SF-36 results for Menière patients, control group, patients with migraine, patients with rheumatoid arthritis, and reference values (see also Table 3).
The knowledge of the specific psychological problems and the quality of life in patients with Ménière's disease, gives us insight as to where, when, and how we should give psychological support. It was seen that Ménière patients with longer disease duration had more daily stressors and worse quality of life in certain dimensions. Statements on changes in the psychological profile occurring over time cannot be made due the cross-sectional character of the study. Furthermore, patients with more severe subjective complaints from their disease had more psychopathology, were more emotionally unstable, and had a worse quality of life. Patients with severe symptomatology did not differ in personality or coping from the ones with mild symptomatology. Therefore, the question why some Ménière patients develop more intense symptoms than others, could not be answered from this study.
Conclusions and recommendations

Menière patients have a deviant psychological profile compared to published normed values, but comparable to patients with other chronic diseases. Many psychological factors and the symptoms of the disease seem to interact. To interfere in this psychological process, we need to break in by reducing the severity of symptoms with hearing aids and medication. Next to that, the psychological support needs to be intensified where needed. The coping and psychopathology (e.g., anxiety and depression) should be approached by a psychologist or a psychiatrist. The impact of the disease on the daily functioning (mental, physical and social) should also be a point of attention. When Menière patients are helped with these issues, they function and feel better, and consequently handle their stressful disease more effectively.
