Abstract

Background: Weight gain and obesity can increase liver transplant (LTx) recipients' disease burden. We aimed to summarize and synthesize the evidence on pre- and post-transplant factors related to post-LTx BMI, weight gain, and obesity.

Methods: For this systematic review and meta-analysis we searched Medline (PubMed), Cochrane library, CINAHL, PsycINFO, and EMBASE for quantitative studies on 6 classes of factors (i.e., genetic, sociodemographic, behavioral, biomedical, psychological, and environmental) linked to body weight parameters in adult first-time LTx patients. A 19-item instrument was used for quality assessment. Odds ratios (ORs) with 95% confidence intervals (CIs) were calculated for relationships investigated in ≥5 studies. Factors investigated in <5 studies were summarized and described.

Results: Of 16,495 articles retrieved, 43 assessed factors in LTx. These examined 82 mainly biomedical and sociodemographic factors. However, variation between definitions allowed inclusion of only 2 factors (i.e., tacrolimus, cyclosporine) in our meta-analyses of 6 studies examining a shared parameter for body weight (median patient sample: 171 (range: 63–455); Europe n = 3; United States n = 3; publication years: 1997–2015). Neither tacrolimus (OR, 0.75; 95% CI, 0.47–1.21; p = 0.24) nor cyclosporine (OR, 1.40; 95% CI, 0.89–2.18; p = 0.14) were related significantly with post-LTx obesity.

Conclusions: Evidence on modifiable factors related to post-LTx body weight parameters is still scarce, as definition variability limits data extraction and pooling for meta-analyses. To facilitate future research, studies should apply theoretical frameworks to guide their study design, select variables of interest and systematically examine interrelationships among selected factors.

1. Background

Obesity, defined as a body mass index (BMI) ≥ 30 kg/m², has become a major health issue in the liver transplant (LTx) population. An analysis of the Scientific Registry of Transplantation Recipients in the United States (US) revealed that, from 2001 to 2011, reflecting a general worldwide trend towards rising BMI values [1], the prevalence of obesity in LTx candidates rose from 29% to 34.4% [2]. Post-LTx weight gain increases this figure further in the recipients. Independent of geographical region or research era, obesity increased from pre-LTx to 1 year post-LTx in studies from the US (14.5% to 23.8%) [3], the United Kingdom (12.6% to 23.7%) [4], and Poland (1.3% to 14.7%) [5]. However, these values must be evaluated carefully, as their reported measurements do not necessarily account for pre-LTx fluid overload (e.g., edema), which biases measurement of BMI, i.e., body weight in kilograms divided by the square of height in meters (kg/m²). As this would falsely inflate the prevalence of obesity at LTx, the rise of its post-LTx prevalence may be even more pronounced. In fact, a recent Swiss prospective cohort study measuring weight gain between 6 months and 3 years post-LTx noted a mean weight gain of 4.8 kg, which increased the prevalence of obesity in their sample from 5.9% to 18.8% [6].

In general, weight gain is the result of complex interactions between biological (including genetic), behavioral, social, and environmental factors [7]. Post-LTx weight gain is often attributed to immunosuppressive medication—especially prednisone, as its side effects include enhanced appetite, a craving for sweets and increased intake of high-fat foods [8,9]. However, not all available evidence supports this relationship [10,11]. Conflicting results have also been reported in view of other biomedical (cyclosporine) [5,11,12], sociodemographic (age and gender) [3–5,11], and behavioral factors (current and former smoking) [3,11,12]. However, a clear understanding of post-LTx body weight factors is important as both weight gain and obesity are associated with metabolic syndrome [13,14]. As the LTx population is already exposed to a higher risk for metabolic and cardiovascular diseases due to immunosuppressive medications [15–19], the possibility that obesity might exacerbate their burden of disease is worrisome.

Examining risk factors for post-LTx body weight parameters offers three main advantages: it identifies patients at risk for weight gain and subsequent obesity; it facilitates understanding of pathways to weight gain; and it exposes modifiable risk factors. Together, these provide a firm basis upon which to develop preventive interventions against weight gain and obesity [20,21]. Therefore, the primary aim of this systematic review and meta-analysis was to summarize and synthesize the evidence regarding pre- and post-LTx risk factors influencing body weight parameters such as BMI, obesity, and weight gain.

2. Methods

The methodology of this systematic review and meta-analysis followed the recommendations of the Cochrane Handbook for Systematic Reviews of Interventions [22]. Reporting was structured according to the Preferred Reporting Items for Systematic Reviews and Meta-Analyses: PRISMA statement [23]. The review protocol was registered in the international prospective register of systematic reviews (PROSPERO, registration number: CRD420...) and published [24].

2.1. Information sources and search strategy

We searched the following electronic databases without limits: Medline via PubMed, Cochrane library, CINAHL, PsycINFO, and EMBASE. To identify relevant additional studies, we screened reference lists of studies included in data extraction. The search string was developed according to PICOS criteria (Participants, Interventions/Exposure, Comparisons, Outcomes/Topics, Study design). To allow a broad variety of search results, search strings were restricted to two concepts: ‘participants’ and ‘exposure’. The first string was developed for PubMed (see Table 1) and later translated for the remaining databases in collaboration with a librarian. The first search was conducted March 17, 2014 and updated February 3, 2016. As the project aimed to examine risk factors related to body weight parameters in kidney, liver, heart and lung transplant populations, the search strategy included all solid organ groups [24]. However, this article only reports the risk factors affecting the LTx population.

2.2. Inclusion and exclusion criteria

Studies were included if they met following criteria: (1) original quantitative or mixed-method study design; (2) first-time liver, heart, lung or kidney transplant candidates or recipients aged ≥18 years;
(3) examination of risk factors or correlates associated with post-LTx body weight parameters; (4) study reported in English, German, Dutch or French; and (5) full text available. Studies with other than original quantitative or mixed-method study design (e.g., case reports, reviews, editorials, letters to the editor, qualitative research), focusing on re-transplanted or multi-organ transplant recipients, or not examining any relationship between body weight parameters and other variables, were excluded.

2.3. Study selection

In accordance with the inclusion and exclusion criteria, title and abstract screening (stage 1) then full text reading (stage 2) were performed by three researchers (SB, GD, NN) for the first search, and by two researchers for the 2016 search update (SB, GD). In both stages of the study selection process, the studies were divided into equal work packages. Each researcher independently evaluated the studies of the allocated work package. For feasibility reasons, as the first literature search retrieved 13,367 hits, we deviated from the Cochrane Collaboration recommendation that at least two people should independently select studies and then verify all results [22]. For quality monitoring, the study selection process was first pilot-tested and evaluated in 50 studies for stage 1 and in 6 studies for stage 2. Researchers then cross-checked a random sample of 10% of one another’s in- and exclusion decisions. Disagreements were resolved by discussions with a third researcher (SDG) until consensus was reached.

2.4. Data extraction and management

Data extraction of the studies included in the meta-analysis was performed independently by two researchers (SB, GD). In cases where an article provided either insufficient data for extracting or conflicting information, the author was contacted for additional information at most twice via e-mail or research network platforms. The following general variables were extracted: general information (author, year, journal, continent, country, language, setting, database, study design, time of transplant), population (donor, etiology of liver disease, model of end-stage liver disease score, sample size, age, gender, race, follow-up time, correction for ascites, definition of BMI categories), details on statistical analysis, and body weight parameters (BMI and BMI category at LTx and post-LTx, as well as post-LTx weight gain). For the purposes of this study, we defined weight categories with the most commonly used BMI classification—that proposed by the World Health Organization (WHO)—as an accurate outcome measure: underweight: <18.5 kg/m²; normal weight: 18.5–24.9 kg/m²; overweight: 25–29.9 kg/m²; and obesity ≥30 kg/m² [25].

As weight gain and obesity result from a complex interplay of factors [7], we used a previous extensive overview [26] to develop a guiding framework, and categorized pre- and post-LTx factors as follows: genetic (e.g., single genes, family history of overweight), sociodemographic (e.g., age, gender, education, marital status, income level, working status), behavioral (e.g., energy intake, energy expenditure, physical activity, smoking), biomedical (e.g., BMI category, end-stage organ disease, hemodialysis, medication), psychological (e.g., stress, quality of life), and environmental (e.g., public transportation, availability of exercise areas).

2.5. Quality assessment

Quality of the meta-analyzed studies was assessed independently by two researchers (SB, GD) via a 19-item instrument (see supplemental digital content, Table 1), which was adapted from two other tools: the 27-item Downs and Black checklist [27] and a quality assessment instrument used for Duerinckx et al.’s 2016 systematic review [28]. The results of the quality assessment were visualized via the Cochrane Risk of Bias summary figure provided by Cochrane Review Manager 5.3 [29].

2.6. Data analysis

Study characteristics were presented using descriptive statistics. Where mean values for age or BMI were only provided for subgroups, a weighted mean was calculated for the total sample. Only risk factors assessed in ≥5 studies were included in the meta-analysis. Effect sizes were calculated to analyze the strengths and directions of relationships, and were expressed as odds ratios (OR) for associations between risk factors and post-LTx body weight parameters. All effect sizes were reported with the corresponding 95% confidence intervals (CIs). Because we expected sample heterogeneity among the primary studies, estimated effects were pooled using a random-effects model. The included studies’ heterogeneity was assessed using both the Cochrane Q test (with a p value <0.1 indicating significant heterogeneity) and I² statistics, with values of 25%, 50%, and 75% respectively indicating moderate low, moderate, and high heterogeneity [30]. Subgroup analyses using year of publication and geographical location as moderators were conducted with meta-analytic versions of regression (for continuous moderators) and ANOVA (for dichotomous moderators). Risk factors assessed in <5 studies were grouped within their categories and classed as significant or nonsignificant based on their relationship with the body weight parameter. The results were summarized graphically. All analyses were conducted using Comprehensive Meta-Analysis software (Biostat, Inc., Englewood, NJ, USA).

3. Results

3.1. Study selection and assignment to the categories

The study selection process is shown in Fig. 1. Of 16,495 initial references, 43 studies in LTx met the inclusion criteria. These assessed 82 distinct pre- and post-LTx factors in relation to any of the 3 body weight parameters (i.e., post-LTx BMI, obesity and weight gain). Overall, factor definitions varied hugely, which limited pooling to groups of at least 5 studies examining the same factor in relation to the same body weight parameter of interest. Two factors (i.e., tacrolimus and cyclosporine) were examined in 6 studies versus post-LTx obesity, making them eligible for data extraction and meta-analysis [13,31–35].

3.2. Summary of factors examined in relation to post-LTx body weight parameters

Fig. 2 shows an overview of factors studied in fewer than 5 studies in relation to post-LTX BMI, obesity and weight gain. The majority of factors examined were categorized as biomedical and sociodemographic. Within the pre-LTX biomedical factors, diabetes mellitus and BMI were studied 5 times in relation to either BMI, obesity or weight gain and represented the highest number of significant results relative to the total number of studies (respectively 3/5 and 5/5). Among the post-LTX biomedical factors of interest, 4 types of immunosuppressive medication were frequently examined in relation to the 3 body weight parameters, but generally yielded low proportions of significant results: steroids (2/12), cyclosporine (2/8), tacrolimus (0/7), and sirolimus (2/3). In the group of pre-LTX sociodemographic factors, gender and age were studied most frequently, both with mixed results regarding their impact (2/7 and 2/5). Very few studies examined behavioral, genetic or psychological risk factors; none examined environmental factors.

3.3. Characteristics of the studies included in meta-analysis

The characteristics of the 6 studies examining tacrolimus and cyclosporine as possible factors of post-LTx obesity are summarized in
Table 2. All 6 were single-center studies from either Europe (n = 3, 50%) or the US (n = 3, 50%), and were published between 1997 and 2015. The median sample size was 171 patients (range, 63–455). Distributions of patients within BMI categories were not provided in all of the studies, nor were BMI category definitions used consistently. The final set of studies did not include companion papers.

3.4. Risk factors for post-LTx obesity

The 6 included studies, involving a total of 1177 participants, showed no association between tacrolimus and post-LTx obesity (OR, 0.75; 95% CI, 0.47–1.21; p = 0.24) (Fig. 3). There was low but non-significant heterogeneity among the studies (Q, 7.12; p = 0.21; I² = 29.75%). A subgroup analysis based on year of study publication did not show a significant result (β = 0.05; p = 0.18); nor did a subgroup analysis based on where each study was conducted (Europe, including Turkey: mean OR, 1.64 95% CI, 0.871–3.088); US: mean OR, 1.15 95% CI, 0.59–2.25; p = 0.45).

Further, no association was shown between cyclosporine use and post-LTx obesity (OR, 1.40; 95% CI, 0.89–2.18; p = 0.14). Heterogeneity among the studies was non-significant (Q = 4.67; p = 0.46; I² = 0.00%). As with the tacrolimus analysis, cyclosporine yielded no significant difference in study effect sizes based on year of publication (β = −0.03, p = 0.34); and no difference was shown due to study location (Europe, including Turkey: mean OR, 1.64 95% CI, 0.871–3.088); US: mean OR, 1.15 95% CI, 0.59–2.25; p = 0.45).

3.5. Quality assessment

The results of the quality assessment are shown in the Supplementary material Fig. 1. All studies had retrospective study designs (n = 6, 100%); four (66.6%) had sample sizes large enough to test individual predictor variables. None used a theoretical framework to guide the research process or the selection of study variables; and none reported studying representative samples (selected via probability sampling). Three studies (50%) clearly described the patient characteristics needed to apply our systematic review’s inclusion and exclusion criteria. All 6 adequately described the results and the variables of interest, i.e., the factors analyzed in relation to body weight parameters. Although 2 (33.3%) took confounders into account, none adjusted adequately for them in the analysis. Based on the methods described in the articles, 3 studies (50%) met the criteria for reproducibility.
Fig. 2. Pre- and post-LTx risk factors of post-LTx obesity, weight gain and BMI assessed by 1 to 4 studies.

4. Discussion

This systematic literature review summarized pre- and post-LTx factors relating to post-LTx BMI, obesity, and weight gain. In all, 82 factors were identified, mainly from the biomedical and sociodemographic categories. Behavioral, genetic or psychological factors were less frequently studied, while environmental factors were not examined in relation to any body weight parameter. As only tacrolimus and cyclosporine were addressed in ≥5 studies, they were the only factors eligible for meta-analysis. Neither tacrolimus nor cyclosporine was significantly associated with post-LTx obesity.

4.1. Examination of factors associated with body weight parameters

All factors were assigned to our predefined categories. As expected, the majority were biomedical or sociodemographic. Most are easily obtainable, as they are among the more common sample characteristics in single-center and database-related studies. In spite of a large initial search return, however, not enough articles were available to perform more meta-analyses, as the researchers’ factor definitions varied too greatly. E.g., steroid use was defined as use of cortisone (yes/no), cumulative steroid dose, length of steroid use, or use of steroids in combination with other immunosuppressive drugs. This level of heterogeneity among definitions precluded meta-analyses to test for relationships between immunosuppressive drugs and weight-gain parameters, which still warrant further investigation.

Following LTx, metabolic comorbidities such as diabetes, hypertension or dyslipidemia commonly occur as side-effects of immunosuppressive medication [17]. Although obesity is also classed as a metabolic disorder, few studies have examined possible relationships with it. Three out of 5 studies focusing on diabetes found that pre-LTx diabetes significantly related to post-LTx obesity and weight gain. Taking another perspective, in a recent systematic review, Li et al. examined risk factors for new-onset diabetes mellitus after LTx by meta-analyzing 7 studies with information on pre-LTx BMI [36]. The results suggest relationships between diabetes and body weight parameters, independent of when those parameters were measured; however, testing these relationships will require further investigation.

Nevertheless, body weight influencing parameters include far more than biomedical or sociodemographic factors. As weight gain and subsequent obesity are driven by multiple interrelated factors, a broader range of variables require consideration [26]. Evidence in the general population stresses the importance of socioeconomic (e.g., female gender with low income) [37,38], psychological (e.g., depression) [39], and genetic factors (e.g., BMI- and obesity-related genes such as FTO, MC4R, or BDNF) [40]. Yet, the examination of those specific factors in large samples is often limited because they are not included per se in standardized database or registry data collection.

Behavioral factors, e.g., healthy eating and physical activity, represent another important component in relation to body weight parameters. Still, while their value to prevent weight gain has been shown in the general population [41,42], evidence in the LTx population is lacking. Two quantitative studies asked LTx recipients their opinions regarding the causes of weight gain after LTx [16,43]. Interestingly, increased food intake, constant hunger, and decreased daily physical activity were among the most common responses. Although these findings suggest that patients perceive behavioral
factors as relevant to weight gain, this relationship needs further examination in both qualitative and quantitative research. Examining barriers to physical activity after transplantation, a small study in kidney recipients found that, alongside fear of injuring the new kidney, health problems such as pain were limiting post-LTx activity levels, as well as time constraints after they returned to work [44]. These findings not only provide preliminary insights regarding post-kidney transplant non-performance of physical activity, but also emphasize behavior’s relationships with other factors (e.g., psychological [i.e., fear, anxiety], biomedical [i.e., pain], and sociodemographic [i.e., return to work]). Given the complexity of factors related to body weight parameters, future research should incorporate theoretical frameworks guiding the choice of study design and selection of variables of interest.

Overall, the alarming low number of studies examining risk factors and body weight parameters in the LTx population indicates an urgent need for further investigation. Yet, methodological issues may be a barrier. Various genetic, sociodemographic, behavioral, biomedical, psychological, and environmental factors (e.g., epigenetic characteristics, monthly income, physical activity, immunosuppressive drugs, moving to another area) can change over the course of Tx. An adequately-sized prospective study cohort that can supply repeated measurements, thereby allowing multivariate analyses and the examination of interrelationships, would be optimal for this type of research.

4.2. Examination of various body weight parameters

Despite the broad choice of body weight parameters available for study, the majority of study authors chose to examine post-LTx obesity (BMI ≥30 kg/m²). However, none differentiated between the WHO’s three obesity classes (class I: BMI ≥30–34.9 kg/m²; class II: BMI 35–39.9 kg/m²; class III: ≥40 kg/m²) [25]. As BMI values ≥35 kg/m² have been associated with lower patient survival [45], higher post-LTx morbidity and increased healthcare utilization [45–47], risk factors associated with obesity classes II and III warrant far more attention.

The small number of studies examining post-LTx weight gain—recognized as a health issue in LTx since the early 1990s [43]—was also somewhat surprising. Modifiable weight gain risk factors could be targeted by preventive interventions, which are widely accepted as the key strategy against weight gain and subsequent obesity [48–50]. The reason for this approach is the so-called yo-yo effect. In times of lower energy intake, e.g., during a diet, compensatory physiological mechanisms lead to reduced energy requirements. Afterwards, when energy intake increases to a normal level, to have a reserve available for future shortages, the body takes up more energy than actually needed, resulting in weight re-gain [51]. Based on the difficulty involved in overcoming these compensatory mechanisms, preventing weight gain should logically be easier than achieving and maintaining a target weight after weight loss [52]. Therefore, we propose the identification of risk factors associated with post-LTx weight gain as an important area for future research.

4.3. Risk factors for post-LTx obesity

The use of neither tacrolimus nor cyclosporine—both calcineurin inhibitors—was associated with post-LTx obesity. Following LTx, tacrolimus has become the immunosuppressive treatment of choice, as it is associated with improved patient and graft survival and reduced rejection [53]. Unfortunately, while functioning well as the major pathway of immunosuppression, calcineurin inhibition has also been associated with the development of metabolic comorbidities such as diabetes mellitus, hypertension, and hyperlipidemia [54]. However, our meta-analysis showed no association between either tacrolimus or cyclosporine and obesity as a metabolic disorder. Moreover, the literature search retrieved 8 studies which examined tacrolimus or cyclosporine with weight gain after LTx, however, none of those found a significant association.

Although heterogeneity was not statistically significant across our sample, the small number of studies included in the analysis (n = 6) might have contributed to an inadequate statistical power to detect differences across studies. Subgroup analyses considering year of study publication and geographical location found no differences.

However, several inter-study methodological and clinical disparities may also have impacted our analyses. First, from a methodological perspective, obesity alone might not be accurate enough as an outcome measure. We did not distinguish in our review between obesity per se (which might have been present pre-LTx) and new-onset obesity that developed post-LTx. Of the studies relevant to our meta-analyses, only Akarsu et al. provided more detailed information about this differentiation, as they examined the factors related to obesity’s development [31]. Second, the cutoff values defining obesity differed across the 6 studies—one of which provided no BMI cutoff [35]. Third, 3 studies were cross-sectional, examining the relationship between immunosuppressive drugs and post-LTx obesity only at one specific time point, i.e., either 1 [13,33] or 3 years [35]. The other 3 assessed post-LTx obesity longitudinally between 1 and 168 months, weakening a precise definition of the outcome measured. Finally, as immunosuppressive medications are core treatment elements, preventing graft rejection after transplant, studies examining them often lack adequate control groups.

From a clinical perspective, the amount of immunosuppressive medication applied likely varied across the 6 studies and over time. Dosing usually decreases in the post-LTx course to minimize long-term medication-related side effects and comorbidities [55]. Also, in case of medication intolerance or other clinical, laboratory, or histological responses, a medication regimen might change radically [17]. Finally, based on a growing body of research and clinical experience, since the first uses of cyclosporine and tacrolimus—respectively in the late 1970s and late 1980s—, their application (i.e., amount of medication needed, combination of drugs) has improved continuously [55]. Considering that the 6 studies included in our meta-analysis studied LTx over ~2 decades (1986–2010), this long-term development process implies heterogeneity in the prescription of both immunosuppressive agents. Neither of these clinical issues (e.g., possible changes of immunosuppressive regimen, dosing) was described explicitly in any of the 6 included studies.

4.4. Limitations

In addition to the shortcomings already mentioned in the discussion, this study has additional limitations. First, as noted, we could only include a small number of observational studies. Results should therefore be interpreted with caution. Second, the definitions and reporting methods varied across all 43 articles examining risk factors. This hindered the extraction of variables needed for the final meta-analysis. Additionally, although we applied no time limit for the search, data extraction from studies performed >10 years ago was sometimes limited due to information missing from reports or articles, as authors did not typically archive their data or respond to requests for additional information. Third, the inclusion criteria that all participants be aged ≥18 led to the exclusion of a number of papers, especially from the earlier transplantation era, when adults were often defined as aged ≥16 years. Fourth, due to a lack of reported data, we were not able to include information on body composition or waist circumference, both of which are important and informative body weight parameters. Finally, due to the small number of eligible studies, we were unable to perform more comprehensive subgroup analyses, examining moderators such as type of transplant, study setting, ethnicity, age, gender, adjustment for ascites or co-morbidities.
5. Conclusion

We identified 82 distinct pre- and post-LTx factors examined in relation to BMI, obesity and weight gain after LTx. The factors studied were mainly categorized as biomedical and sociodemographic. Unfortunately, strong variations in factor definitions limited the pooling to groups of at least 5 studies for meta-analysis. Only two factors were eligible for meta-analysis: tacrolimus and cyclosporine. Neither was significantly associated with post-LTx obesity. Subgroup analyses focusing on year of publication and geographical region yielded no significant results. Further research is necessary to identify modifiable factors associated with post-LTx weight gain and obesity, to facilitate development of preventive interventions. Future studies should apply theoretical frameworks to select variables of interest and systematically examine interrelationships among different factors.

Conflicts of interest

None.

Funding

This systematic review received funding by the 2014 International Transplant Nurses Society research grant. The funding source was neither involved in the research nor preparation of the article.
