Chapter 2

Optimal Dual-VENC (ODV) Unwrapping in Phase-Contrast MRI

2.1 Introduction

Velocity-encoded Phase-Contrast MRI (PC-MRI) is a well-established method for measuring flow velocities, with several applications to quantitative analysis of cardiovascular pathologies [Sri+09]. The velocity-encoding magnetic gradients are set by the choice of the velocity encoding parameter, or VENC [Dyv+15]. It is well known that the velocity-to-noise-ratio (VNR) worsens when increasing the VENC. However, if VENC is set lower than the true velocity (which is unknown prior to the scan), velocity aliasing occurs. Moreover, even for VENC values slightly larger than the true velocity, velocity aliasing may occur due to measurement noise. These restrictions motivate in clinical practice to acquire images at different VENCs, obligating the MRI operator to manually select the image for one specific VENC, while the aliased images are ignored and the time spent is squandered.

Velocity aliasing is one of the main limitations for measuring complex features of blood flows, particularly, when high and low velocities are present in the same image, such as in heart, valvular and vascular malformations.

Then, VENC has to be set high, but as a consequence, low VNR is present in low velocity regions, for instance in recirculation regions in aneurisma or false lumen in dissections, to name a few. This leads to significant inaccuracies when further analysis of the flow is performed [Cal+16]. Aliasing is also prob-
lematic in many PC-MRI techniques, like Tissue Phase Mapping [Pet+06] and Elastography [HSB17], where the motion magnitudes vary across the regions of interest.

In order to reduce aliasing artefacts, unwrapping algorithms have been developed by assuming that the velocity field is smooth in space and/or time, see e.g. [Loe+16] and references therein. Nevertheless, they often fail when the aliased regions are large. Therefore, voxelwise dual-VENC strategies have been proposed, i.e. without any assumption on smoothness of the flow [LPP95; Net+12; Ha+16; Cal+16; Sch+17]. They have been based on unwrapping low-VENC data by using the high-VENC reconstruction, which is assumed aliasing-free. While actual approaches allow to improve the VNR with respect to a single high-VENC acquisition, they fail when the high-VENC data is aliased. Also, there is a lack of mathematical support for choosing the low- and high-VENCs. All of these issues limits the applicability of dual-VENC techniques, particularly when the peak velocities are uncertain.

Therefore, the aim of this work is to provide a mathematical framework to obtain aliasing-free velocity estimations from dual-VENC data, even when both VENC acquisitions are aliased. The key is the least-squares formulation of the PC-MRI problem, whose mathematical properties allow to propose optimal combinations of VENCs to achieve this goal. We also present a numerical algorithm for dual-VENC reconstructions, which is successfully applied to numerical, experimental and volunteer data sets.

2.2 Theory

2.2.1 Classical PC-MRI

Assuming a constant velocity field, the usual starting point of classical PC-MRI is the model for the phase of the transverse magnetization at the echo-time [LPP95]:

$$\varphi^G = \varphi^0 + \vartheta^G$$  \hspace{1cm} (2.1)

with $\varphi^0 \in [0, 2\pi)$ the reference phase, and

$$\vartheta^G = \vartheta^G(u) = \gamma u m_1(G)$$  \hspace{1cm} (2.2)

the velocity dependent phase. Here, $u \in \mathbb{R}$ the flow velocity component parallel to the velocity-encoding gradient $G = G(t) \in \mathbb{R}$, with $t$ the encoding time, and $m_1(G) \in \mathbb{R}$ the first-order moment of $G(t)$. The constant $\gamma > 0$ is the giromagnetic ratio.

From now on, we deal with different gradients $G_i$ with different amplitudes. Assuming that we have measured two phases $\varphi^{G_0}$ and $\varphi^{G_1}$ with $G_0 \neq G_1$, the phase-contrast velocity is estimated by

$$u_{pc} := \frac{\varphi^{G_0} - \varphi^{G_1}}{\pi} \text{VENC}(G_0, G_1),$$  \hspace{1cm} (2.3)
2.2. THEORY

with
\[ \text{VENC}(G_0, G_1) = \frac{\pi}{\gamma(m_1(G_0) - m_1(G_1))}. \]

In the case that the true velocity \(|u_{\text{true}}| \leq |\text{VENC}|\), then \(u_{pc} = u_{\text{true}}\). But if \(|u_{\text{true}}| > |\text{VENC}|\), the phase difference exceeds \(\pm \pi\) and aliasing occurs, i.e. \(u_{\text{true}} \neq u_{pc}\). However, increasing the VENC decreases the VNR. Therefore, choosing the VENC parameter is an iterative manual process trying to set it as small as possible to maximize VNR and at the same time large enough to avoid aliasing.

2.2.2 Dual-VENC approaches

It is well known that for any VENC value, \(u_{\text{true}}\) belongs to the set of infinite but numerable solutions of type
\[ u_{pc} + 2k\text{VENC}(G_0, G_1), \quad k \in \mathbb{Z}. \quad (2.4) \]

Therefore, it is natural to extend the velocity estimation problem such that \(k\) can be also estimated using additional encoding gradient measurements.

Assuming that now three measurements with gradients \(G_0 = 0 < G_1 < G_2\) are available, two velocities at different VENC values can be reconstructed: the phase-contrast velocity \(u_1 = \text{VENC}(G_1, 0)\) and a set of velocities \(u_2 + 2k\text{VENC}_2\) at \(\text{VENC}_2 = \text{VENC}(G_2, 0)\), with \(\text{VENC}_1 > \text{VENC}_2\), \(k \in \mathbb{Z}\), where \(u_2\) is obtained by phase-contrast at \(\text{VENC}_2\). Standard dual-VENC unwrapping strategies, see e.g. [Sch+17; LPP95], aim to find the correct low-VENC velocity from an un-aliased high-VENC velocity \(u_1\). Hence, an improved VNR should be achieved. Here, we will compare our new dual-VENC approach against the one from [Sch+17], which is defined as:

\[ u_{\text{SDV}} = \begin{cases} 
  u_2 + 2 \cdot \text{VENC}_2 & \text{if } \epsilon_1 < D < \epsilon_2 \\
  u_2 - 2 \cdot \text{VENC}_2 & \text{if } -\epsilon_2 < D < -\epsilon_1 \\
  u_2 + 4 \cdot \text{VENC}_2 & \text{if } \epsilon_3 < D < \epsilon_4 \\
  u_2 - 4 \cdot \text{VENC}_2 & \text{if } -\epsilon_4 < D < -\epsilon_3 
\end{cases} \]

with \(D = u_1 - u_2; \epsilon_1 = 1.6 \cdot \text{VENC}_2; \epsilon_2 = 2.4 \cdot \text{VENC}_2; \epsilon_3 = 3.2 \cdot \text{VENC}_2; \epsilon_4 = 4.8 \cdot \text{VENC}_2\). In the reminder of this article, we will denote it as standard dual-VENC (SDV).

Note that the SDV reconstruction will be aliased if \(|\text{VENC}_1| < |u_{\text{true}}|\). The new dual-VENC method based on our analysis will overcome this issue by optimally choosing both \(\text{VENC}_1\) and \(\text{VENC}_2\) based on a reformulation of the phase-contrast problem presented next.
2.2.3 Least-squares formulation of the single-VENC problem

For a given velocity encoding gradient \( G \) let us denote the measured phase of transverse magnetization by \( \hat{\varphi}^G \).

Assume now that we have available two measurements: a reference one for \( G = 0 \), and another for \( G \neq 0 \). We formulate the velocity reconstruction as a standard maximum-likelihood estimation problem from the phase measurements, by means of the least-squares function

\[
J_G(u) = \frac{1}{2} |e^{i\hat{\varphi}^G} - e^{i\varphi^G(u)}|^2
\]

\[
= \frac{1}{2} \left( \cos(\hat{\varphi}^G) - \cos(\varphi^G(u)) \right)^2 + \frac{1}{2} \left( \sin(\hat{\varphi}^G) - \sin(\varphi^G(u)) \right)^2
\]

\[
= \left(1 - \cos(\hat{\varphi}^G - \varphi^G(u))\right)
\]

with \( \hat{\varphi}^G = \hat{\varphi}^G - \hat{\varphi}^0 \) the “measured” velocity dependent phase.

Least-squares formulations have also been recently applied in the context of unwrapping methods using the information of contiguous voxels for various types of single- and dual-VENC acquisitions [LE17]. However, no analysis of their properties or potential for optimizing the VENC combinations was reported.

Figure 2.1 shows examples of the functions \( J_G(u) \), for different gradients represented by VENC\((G, 0)\). The synthetic measurements were generated with a unitary magnitude and the phases from Equation (2.1) using \( \varphi^0 = \gamma B t_E \) with \( B = 1.5 \) \( T \), \( \gamma = 267.513e3 \) rad/T/ms, \( t_E = 5 \) ms, a velocity \( u_{true} = 1 \) m/s. It can be appreciated that the functions are periodic, with the period depending on the VENC, and also that the true velocity is a local minimum independent on the VENC. The following propositions proof these observations.

![Figure 2.1: cost functions \( J_G(u) \) for \( u_{true} \) and two VENC values.](image)
**Proposition 2.1.** $J_G(u)$ is a periodic function with period $2VENC(G, 0)$.

*Proof.* It suffices to see that the cosine and sine are $2\pi$-periodic functions, and

$$
\vartheta^G(u + 2VENC(G, 0)) = \vartheta^G(u) + 2\pi
$$

**Proposition 2.2.** The critical points $u_k$ of $J_G(u)$ are

$$
u_k = \frac{\hat{\vartheta}^G - \hat{\vartheta}^0}{\gamma m_1(G)} + kVENC(G, 0), \ k \in \mathbb{Z}
$$

*Proof.* From (2.6) we see that

$$
\frac{\partial J_G}{\partial u} = -\gamma m_1(G) \sin(\hat{\vartheta}^G - \vartheta^G).
$$

At the critical points we must then have:

$$
\sin(\hat{\vartheta}^G - \vartheta^G) = 0 \iff \vartheta^G(u_k) = \hat{\vartheta}^G + k\pi, \ k \in \mathbb{Z}.
$$

Finally, using Equation (2.2) we obtain

$$
u_k = \frac{\hat{\vartheta}^G - \hat{\vartheta}^0}{\gamma m_1(G)} + k\frac{\pi}{\gamma m_1(G)}.
$$

**Proposition 2.3.** At the critical points of $J_G(u)$, the second derivatives are given by

$$
\frac{\partial^2 J_G}{\partial u^2}(u_k) = C \cdot (-1)^k, \ k \in \mathbb{Z}, C > 0.
$$

*Proof.* Taking the derivative in (2.8) we obtain:

$$
\frac{\partial^2 J_G}{\partial u^2}(u_k) = \gamma^2 m_1(G)^2 \cos(\hat{\vartheta}(u_k) - \vartheta^G) = C \cdot (-1)^k
$$

where the last equality holds due to Equation (2.9).

In conclusion, we have just proved that Equation (2.4) corresponds to the local minima of the cost function $J_G$ by taking $k$ as an even number in Equation (2.11).

It is also straightforward to show that the true velocity $u_{true}$ belongs to the set of local minima of $J_G$ when the measurements are noise-free. Indeed, in that case $\vartheta^G = \vartheta^0 + \gamma m_1(G)u_{true} + 2k\pi$, and if we choose $\vartheta^G(u_{true}) = \vartheta^0 + \gamma m_1(G)u_{true}$, then $J_G(u_{true}) = 0$ from Equation (2.6).
2.2.4 The dual-VENC least squares problem

We assume now that we have measured the magnetization vector with three encoding gradients \( G_0 = 0 < G_1 < G_2 \). We can then define the dual-VENC least squares sum function as:

\[
J_\Sigma(u) = \frac{1}{2} \sum_{j=1}^{2} |e^{i\hat{\theta}G_j} - e^{i\theta G_j(u)}|^2 \\
= \sum_{j=1}^{2} \left(1 - \cos \left(\hat{\theta}G_j - \vartheta G_j(u)\right)\right)
\]

Figure 2.2 shows the single- and dual-VENC least-squares functions for different VENC combinations \( VENC_1 > VENC_2 = \beta VENC_1, \, 0 < \beta < 1 \). Hence, the VENCs can be set in terms of \( VENC_1 \) and \( \beta \). Note that \( VENC_1 \) is set lower than \( u_{true} \) and is kept fixed in all plots, while \( \beta \) is variable. We can first observe that in all cases local and global minima are present in the dual-VENC functions \( J_\Sigma(u) \). However, the true velocity is always a global minimum since it is a local and global minimum for each VENC, as shown in the previous section.

Remarkably, the periodicity of \( J_\Sigma \) is now the least common multiplier (lcm) between the periodicity of the single-VENC functions, i.e. \( L_\Sigma := \text{lcm}(2VENC_1, 2VENC_2) \). As a consequence, if \( \beta \) is carefully chosen, as in Figure 2.2(a) and 2.2(b), \( J_\Sigma \) has a larger period than the original single-VENC functions, namely \( L_\Sigma > 2VENC_1 \). Therefore, even though \( VENC_1, VENC_2 < |u_{true}| \), we can still distinguish \( u_{true} \) from the other global minima since they have larger absolute values.

However, if we do not choose \( \beta \) well, e.g. as in Figures 2.2(c) and 2.2(d), then \( L_\Sigma = 2VENC_1 \) and the global minima with smallest absolute value will not be \( u_{true} \) if \( VENC_1 < u_{true} \) and velocity aliasing occurs. A general method for computing the aliasing limit is: for \( \beta = \alpha/\alpha_0 \), with \( \alpha, \alpha_0 \in \mathbb{N} \) the smallest possible values, then it is easy to verify that the periodicity of \( J_\Sigma \) is \( L_\Sigma = \alpha 2VENC_1 \), since

\[
L_\Sigma = k_1 2VENC_1 = k_2 2\beta VENC_1, \, k_1, k_2 \in \mathbb{Z}
\]

leading to \( k_1 = \alpha, \, k_2 = \alpha_0 \). Then, aliasing will occur when \( |u_{true}| - L_\Sigma/2| < |u_{true}|, \) i.e. \( VENC_1 < |u_{true}|/\alpha \).

Table 2.1 gives examples of \( VENC_1 \) such that the global minimum of \( J_\Sigma \) with lowest magnitude corresponds to \( u_{true} \) depending on \( \beta \).

2.2.5 Choice of \( \beta \)

As shown in Table 2.1, in the case without any measurement noise, to maximize the periodicity of \( J_\Sigma \) one should choose \( VENC_2 \approx VENC_1 \), making the aliasing
Figure 2.2: Cost functions $J_G(u)$ and $J_Σ(u)$ for different VENC$_1$, VENC$_2 = β$VENC$_1$.

\( β \) & 0.95 & 0.9 & 0.75 & 0.7 & 0.66 & 0.55 & 0.5 \\
\hline
\( α \) & 19 & 9 & 3 & 7 & 2 & 11 & 1 \\

Table 2.1: Examples of aliasing limits for decreasing values of $β$. ODV method allows aliasing-free estimation if VENC$_1 > |u_{true}|/α$.

However, the presence of noise deforms the dual-VENC functions, see Figure 2.3, since the noise is independent for each VENC. Therefore, local minima from both single-VENC cost functions that are not necessarily $u_{true}$ can get close to each other. Hence, there is an increased risk for $u_{true}$ not being global minima when $α$ is large. In order to maximize the robustness to noise, the local minima of both single-VENC functions should be separated as much as possible. As shown in Figure 2.2(b), this is indeed the case for $β = 0.66$. For $β = 0.75$ this separation is less pronounced, however $β = 0.75$ would allow to lower the aliasing velocity if noise is low. In general, the optimal choice of $β$ should be optimized to the SNR of the specific MRI scanner, but $β = 0.66$ is
always the most robust to noise due to the largest separation between minima. In the experiments, we will use these two values, $\beta = 0.66$ and $\beta = 0.75$. Additionally, in the experiments with numerical data, we will show the poor performance of $\beta = 0.7$ when noise is present.

Figure 2.3: Cost functions $J_G(u)$ for different pair of values of VENC and the sum cost function $J_\Sigma$ with noisy magnetization measurements (standard deviation 20% of magnitude).

### 2.2.6 The optimal dual-VENC (ODV) algorithm

Based on the considerations above, we now detail the ODV velocity estimation algorithm. For the given user-defined parameters VENC$_1$ and VENC$_2 = \beta \text{VENC}_1$, $0 < \beta < 1$:

1. Measure phases $\phi^{G_i}$ for three gradients: $G_0 = 0$ and $G_1$, $G_2$ such that $\text{VENC}(G_1, 0) = \text{VENC}_1$ and $\text{VENC}(G_2, 0) = \text{VENC}_2$.

2. Find the global minima $u^*_k$, $k \in \mathbb{Z}$:

   $$u^*_k = \arg\min_{u \in [-u_{\text{max}}, u_{\text{max}}]} J_\Sigma(u),$$

   with $u_{\text{max}} = \text{lcm}(2\text{VENC}_1, 2\text{VENC}_2)/2$. The estimated dual-VENC velocity corresponds to $u^*_k$ with smallest absolute value.
2.3 Methods

This section summarizes setups with three types of data: synthetic, phantom and volunteer. In all cases we applied the formula (2.3) for single-VENC and dual-VENC with both standard [Sch+17] (SDV) and new ODV methods. For the ODV algorithm, the global minima was found using a sampling of the cost function $J_\Sigma$ with uniform spacing of the velocity of VENC. $2 \cdot 10^{-3}$, which was found to be small enough to avoid numerical artefacts in the global optimization.

2.3.1 Synthetic data

The reference phase is defined as $\varphi^0 = \gamma B_0 T_E$ with $B_0 = 1.5 \ T$, $\gamma = 267.513e3 \ rad/T/\text{ms}$, $T_E = 5 \ \text{ms}$. For the phases of the non-zero flow encoding gradients, we consider $\varphi^{G_1,2} = \varphi^0 + u_{true} \pi/VENC_{1,2}$, with $u_{true} = 1 \text{m/s}$.

Using these phases, reference magnetization measurements were built assuming a unitary magnitude. The estimation is shown in terms of VENC and $VENC_2 = \beta VENC_1$, with $\beta = \{0.66, 0.7, 0.75\}$.

We also compute estimations using magnetization measurements perturbed with an additive Gaussian noise with zero-mean and standard deviation of 20% of the magnitude. We express these results in terms of mean estimated velocity for 2000 realizations of the noise and twice the standard deviation.

2.3.2 Phantom data

In order to preliminarily assess the ODV we used a flow phantom that consisted of a rigid straight hose of 15mm internal diameter, 25mm external diameter. The hose was connected to a MRI-compatible flow pump (CardioFlow 5000 MR, Shelley Medical Imaging Technologies, London, ON, Canada) with a constant flow rate of 200 mL/s. The system was filled with a blood-mimicking fluid (40% distilled H2O, 60% Glycerol) and the set up was similar as in [Urb+16; Mon+17]. The MRI data sets were acquired on a clinical 1.5T Philips Achieva scanner (Philips, Best, The Netherlands). The protocol consisted of through-plane PC-MRI sequence with a single cardiac phase due to constant flow rate. The scan parameters were: in-plane resolution was 1x1 mm with a slice thickness of 8 mm, 1 prospective cardiac phase, $FA = 12^o$, $TR=9.2 \ \text{ms}$, $TE=4.9 \ \text{ms}$, matrix size = (256,256). The data was acquired using non-symmetric pairs of encoding gradients with $VENC = 150, 100, 70 \ \text{cm/s}$ with one surface coil. The acquisitions were performed using single-VENC protocols and the dual-VENC reconstructions were computed using only one of the zero-encoding gradients of the corresponding dual-VENC pair.
2.3.3 Volunteer data

Eight healthy volunteers underwent MRI in the same 1.5T Achieva scanner using a 5 elements cardiac coil. The protocol consisted of through-plane PC-MRI sequence perpendicular to the ascending aorta just above the valsalva sinus. We used several VENC values: 33.3, 37.5, 50, 66.7, 75, 100 and 150 cm/s. These choices allow to generate dual-VENC reconstructions with both values of $\beta = 0.66$ and $\beta = 0.75$. The raw data was obtained and the reconstruction of each bipolar gradient was performed offline using matlab. Data from the multiple coils were combined using the method proposed in [Ber+94]. The data was acquired using the following scan parameters: in-plane resolution was 1x1 mm with a slice thickness of 8 mm, 25 cardiac phases using prospective ECG triggering, FA = 15°, TR=5.5 ms, TE=3.7 ms, matrix size = (320, 232). Temporal resolution depended on the heart rate of the patients, varying between 35 ms to 48 ms.

As in the panthom, the acquisitions were performed using single-VENC protocols. One issue with this approach is that the TE may be different depending in the scan setting, particularly may increase for low VENCs [BSP92]. Since we use only the reference phase of VENC$_1$, the value of the reference phase used in the dual-VENC reconstructions for VENC$_2$ was scaled by $T_E^{(2)}/T_E^{(1)}$, with $T_E^{(1)}$ and $T_E^{(2)}$ the echo times given by acquisitions with VENC$_1$ and VENC$_2$, respectively. This is justify simply by the knowledge about the reference phase being proportional to $T_E$ [Bro+14].

2.4 Results

2.4.1 Synthetic data

Figure 2.4 shows the estimated velocity against VENC$_1$ without noise, confirming the unwrapping properties of both dual-VENC approaches: for SDV aliasing occurs when VENC$_1 < u_{true}$, and for ODV when VENC$_1 < u_{true}/2$, VENC$_1 < u_{true}/7$ and VENC$_1 < u_{true}/3$ with $\beta = 0.66$, $\beta = 0.7$ and $\beta = 0.75$, respectively.

Similar results for noisy measurements are presented in Figure 2.5, now including the aforementioned confidence interval. As one expects, the spread of the estimations are lower for $\beta = 0.66$. Moreover, in the single-VENC cases we confirm that aliasing starts even before the theoretical value due to the noise. This is also evident for SDV, while ODV is clearly more robust. We can also see that for ODV and $\beta = 0.7$ the confidence interval does not decrease uniformly with VENC$_1$ due to the nondesirable effect of overlapping of the single-VENC least squares functions mentioned in Section 2.2.5. A similar, but less pronounced effect, occurs with $\beta = 0.75$. Therefore, in the real data acquisitions we continue using only $\beta = 0.66$ and $\beta = 0.75$. 

Figure 2.4: Synthetic data (noise-free): single- and dual-VENC.
Figure 2.5: Synthetic data (20% noise): single- and dual-VENC.
2.4. RESULTS

2.4.2 Phantom data

The results for the phantom experiments are presented in Figure 2.6. The peak velocity in the tube is about 120 cm/s, what can be inferred from the single-VENC image with VENC$_1$ = 150. The wall of the tube can be distinguish as the noise ring separating the flow and the surrounding zero-velocity fluid. We first show the single-VENC PC-MRI, where aliasing for the two smaller VENCs can be clearly appreciated. We also confirm that SDV cannot handle the aliasing when both VENC values are lower than the true velocity, while ODV is able to successfully reconstruct un-aliased images from two aliased ones.

Figure 2.6: Phantom data: single- (PC) and dual-VENC.
2.4.3 Volunteers data

Figure 2.7 presents the velocity profiles on the descending aorta for the different VENC combinations and different reconstruction methods for Volunteer 5. The figures for all the volunteers can be found in the Supplementary Material 2.A.

![Velocity profiles for Volunteer 5](image)

Figure 2.7: Volunteer 5. First row: single-VENC PC-MRI. Second row: SDV. Third row: ODV. Velocities are colored as in Figure 2.6. Numbers indicate the VENC(s).

In all our results in volunteers it is confirmed that ODV is the most robust method when decreasing the VENC, allowing to reconstruct velocities using lower VENCs than the true velocity, in contrast to SDV. Moreover, the theory is verified: aliasing is practically inexistent for \((VENC_1, VENC_2) = (50, 37.5)\) \((\beta = 0.75)\), while aliasing always occurs at \((50, 33.3)\) \((\beta = 0.66)\). Indeed, the peak velocity is approximately 130 cm/s, for \(\beta = 0.75\), \(VENC_1 = 50 > 130/3 \approx 40\), hence no aliasing appears. For \(\beta = 0.66\), \(VENC_1 = 50 < 130/2 \approx 65\), hence aliasing appears. The actual noise level of the acquisition seems to not affect the performance of the ODV with \(\beta = 0.75\).

Figure 2.8 summarises the ODV results for all volunteers when varying the VENC. The error is computed in terms of the \(\ell^2\)-norm for the voxels inside the lumen, relative to the \(\ell^2\)-norm of the reference image (average of VENC 150 cm/s with 3 repetitions).

Finally, Figure 2.9 shows the standard deviation of the estimated velocities on a static tissue (thoracic muscle) in terms of the VENC for all single- and dual-VENC methods. Analogous results are obtained for all volunteers (see Supplementary Material). Here, results need to be carefully analyzed and
2.4. RESULTS

Interpreted. Therefore, we present two sets of dual-VENC reconstructions: one with three encoding gradients as described above scaling the reference phase with the echo times, and another using four encoding gradients, i.e., where the reference phase of each VENC was used and therefore no scaling is needed.

First, we can see that noise decreases with VENC in the single-VENC reconstructions, and that the standard deviation is larger for VENC$_1$ than for VENC$_2$, as expected. For the both dual-VENC approaches, this is also the case for VENC$_2 > 50$ cm/s. The ODV using three gradients (ODV(3)) gives also a standard deviation close to VENC$_2$. Also as expected, the SDV using four gradients (SDV(4)) gives exactly the same results as VENC$_2$.

For VENC$_2 \leq 50$, the standard deviation of both dual-VENC approaches shows jumps when using three gradients, while it monotonically decreases when using four gradients. A possible reason is the scaling of the reference phase for VENC$_2$. Indeed, for VENC > 50 $T_E$ stays fixed, hence no scaling is applied. But for VENC $\leq 50$ the $T_E$ is automatically changed. The differences in the curves for SDV(3) (i.e. with scaling) and SDV(4) (i.e. no scaling) are more evidence pointing in this direction. Therefore, this problem is most likely to be related to the acquired data but not to the ODV or SDV reconstruction methods. We are currently working in dual-VENC acquisition protocols using only three gradients, which should avoid this issue.

Figure 2.8: Volunteers 1 to 8: (VENC$_1$, VENC$_2$) v/s relative error between ODV and reference.
2.5 Discussion

In this work, we present a method for reconstructing velocities using dual-VENC images, for the first time in the literature when both single-VENC images are aliased. The main advantage of the method is that the true velocity does not need be known exactly in advance, since aliasing is allowed for both VENCs. All previous works have proposed to unwrap low-VENC images using high-VENC images without aliasing [LPP95; Net+12; Ha+16; Cal+16; Sch+17]. The theoretical findings are confirmed in real data sets from an experimental phantom and volunteers.

The choice of the VENC’s ratio $\beta = 0.66$ is the most robust to noise, independent on the MRI scanner settings. However, for the volunteers scanned here, $\beta = 0.75$ works satisfactory and therefore it allows lower aliasing limits for the ODV estimations than $\beta = 0.66$, as given by the theory. Let us recall that $\beta$ can be kept fixed (for instance, optimized once for typical scan settings), while the scanner user only needs to choose VENC$_1$ as in a single-VENC acquisition.

Note that unwrapping methods using contiguous voxels - like the ones from [LE17] - can be still applied after the estimation with ODV. The unwrapping would then probably perform better due to the larger periods of the candidate solutions, e.g. $L_\Sigma = 6\text{VENC}_1$ for $\beta = 0.75$ and $L_\Sigma = 4\text{VENC}_1$ for $\beta = 0.667$.

Concerning the limitations of our study, the method was not assessed in
patients, only in volunteers. It is well known that dual-venc approaches (as any other cardiovascular MRI sequences) are challenging due to variabilities during the experiment (not only measurement noise) [LPP95], such as cardiac rhythm changes and subjects’ motion. However, this variability will impact in similar manner the standard dual-VENC approach as well as the method proposed here. Another limitation is that data acquisition was performed for the two VENCs in a serial fashion, and therefore MRI scan protocols tailored to the ODV reconstructions have to be developed yet. This could be also done by including k-space undersampling techniques as in [Net+12], what would allow dual-VENC protocols comparable in scan time to single-VENC ones, what is of high interest for the application of ODV to 4Dflow. Moreover, as in standard PC-MRI, there is the implicit assumption that the velocity is constant in space and time and therefore, neither the single- nor the dual-VENC approaches count for effects like dephasing of spins and turbulence.

2.6 Conclusion

We present a robust method for estimating velocities from dual-VENC data in PC-MRI. The main contribution of this work is that both a theoretical and an extensive empirical analysis was carried out, turning out that there are high- and low-VENC combinations that can considerably reduce the aliasing issues. For example, in the volunteer data the ODV allows to choose the high-VENC up to a third of the maximal velocity. In clinical practice, the scanner operator has only to choose a single expected velocity, as for standard single-VENC PC-MRI. Then, the low-VENC value can be automatically fixed by the scanner in terms of the high-VENC. Moreover, the reconstruction method is simple enough to be implemented directly in the MRI scanner. Next steps are to assess the ODV in cases with high velocity variability, like stenotic vessels or valves, and 4Dflow, and application to other phase-contrast techniques, like elastography.
Appendix

2.A Supplementary material

In this appendix of Chapter 2 we show the velocity profiles on the descending aorta for the different VENC combinations and different reconstruction methods for eight volunteers. The profiles are shown in Figures 2.10, 2.11, 2.12, 2.13, 2.14, 2.15, 2.16, 2.17.

Figure 2.10: Volunteer 1. First row: single-VENC PC-MRI. Second row: SDV. Third row: ODV. Velocities are colored as in Figure 2.6. Numbers indicate the VENC(s).
CHAPTER 2. OPTIMAL DUAL-VENC IN PHASE-CONTRAST MRI

Figure 2.11: Volunteer 2. First row: single-VENC PC-MRI. Second row: SDV. Third row: ODV. Velocities are colored as in Figure 2.6. Numbers indicate the VENC(s).

Figure 2.12: Volunteer 3. First row: single-VENC PC-MRI. Second row: SDV. Third row: ODV. Velocities are colored as in Figure 2.6. Numbers indicate the VENC(s).
Figure 2.13: Volunteer 4. First row: single-VENC PC-MRI. Second row: SDV. Third row: ODV. Velocities are colored as in Figure 2.6. Numbers indicate the VENC(s).

Figure 2.14: Volunteer 5. First row: single-VENC PC-MRI. Second row: SDV. Third row: ODV. Velocities are colored as in Figure 2.6. Numbers indicate the VENC(s).
CHAPTER 2. OPTIMAL DUAL-VENC IN PHASE-CONTRAST MRI

Figure 2.15: Volunteer 6. First row: single-VENC PC-MRI. Second row: SDV. Third row: ODV. Velocities are colored as in Figure 2.6. Numbers indicate the VENC(s).

Figure 2.16: Volunteer 7. First row: single-VENC PC-MRI. Second row: SDV. Third row: ODV. Velocities are colored as in Figure 2.6. Numbers indicate the VENC(s).
Figure 2.17: Volunteer 8. First row: single-VENC PC-MRI. Second row: SDV. Third row: ODV. Velocities are colored as in Figure 2.6. Numbers indicate the VENC(s).
