\begin{abstract}
Roll stabilization is an important problem of ship motion control. This problem becomes especially difficult if the same set of actuators (e.g., a single rudder) has to be used for roll stabilization and heading control of the vessel, so that the roll stabilizing system interferes with the ship autopilot. Finding the “trade-off” between the concurrent goals of accurate vessel steering and roll stabilization usually reduces to an optimization problem, which has to be solved in presence of an unknown wave disturbance. Standard approaches to this problem (loop-shaping, LQG, $H_{\infty}$-control etc.) require to know the spectral density of the disturbance, considered to be a “colored noise”. In this paper, we propose a novel approach to optimal roll stabilization, approximating the disturbance by a polyharmonic signal with known frequencies yet uncertain amplitudes and phase shifts. Linear quadratic optimization problems in presence of polyharmonic disturbances can be solved by means of the theory of universal controllers developed by V.A. Yakubovich. An optimal universal controller delivers the optimal solution for any uncertain amplitudes and phases. Using Marine Systems Simulator (MSS) Toolbox that provides a realistic vessel’s model, we compare our design method with classical approaches to optimal roll stabilization. Among three controllers providing the same quality of yaw steering, OUC stabilizes the roll motion most efficiently.
\end{abstract}

1. Introduction

Roll stabilization is a classical problem in ship motion control (Fossen, 1994; Perez, 2006; Perez and Blanke, 2012). Passive roll stabilization can be provided by special equipment such as bilge keels, water-tanks and moving weights (Perez, 2006; Perez and Blanke, 2012; Marzouk and Nayfeh, 2009); however, these devices cannot be easily adapted to the unsteady environment and the changing wave’s spectrum. This limitation can be overcome by active (controlled) roll stabilization, which can be provided by gyroscopic stabilizers, stabilizing fins and/or actuators (rudders and thrusters) used for the vessel’s steering. This is illustrated by the \textit{rudder roll stabilization} (RRS), proposed originally for a vessels equipped with a single rudder (Cowley and Lambert, 1972; Carley, 1975; Lloyd, 1975). Since fins, rudders and thrusters affect both yaw and roll motion of the vessel, the roll stabilization controller should be integrated with the heading controller (autopilot). These control systems can share some actuators and pursue concurrent goals of roll stabilization control and course steering.

A vessel’s coupled yaw-roll motion can be modeled by a dynamical system, whose inputs are the rudder’s and fins’ angles and whose outputs stand for the ship’s heading and roll. After linearizing this model, classical methods of linear control, e.g., loop shaping and Quantitative Feedback Theory (Cowley and Lambert, 1972; Carley, 1975; Horowitz and Sidi, 1978; Blanke and Christensen, 1993; Hearns and Blanke, 1998) can be applied to stabilize yaw and roll motion. To cope with non-linearities, methods of feedback linearization and sliding mode control can be used (Lauvdal and Fossen, 1997; Liu et al., 2016). For vessels equipped with fin stabilizers, classical methods usually decouple the roll motion from the yaw motion (Surendran et al., 2007; Hinostroza et al., 2015). However, ignoring internal cross-couplings often reduces the overall performance (Carley and Duberley, 1972).

The roll dynamics of a vessel appear to be non-minimum phase, leading thus to the \textit{fundamental limitation} (Carley, 1975; Goodwin et al., 2000): a controller stabilizing the vessel’s heading cannot fully

attenuate the wave-induced roll oscillations. A natural question arises, namely which level of the roll oscillation stabilization can be provided without deteriorating the yaw control. Mathematically, the latter goal is usually formulated as optimality of a special performance index, which penalizes the time-averaged steering error, roll angle and the control effort. Besides the control input, such a functional implicitly depends on the uncertain wave disturbance that affects the ship’s motion. Unlike the aforementioned stabilization techniques, optimization-based algorithms assume that some model of the disturbance is known. Most typically, the wave-induced motion is approximated by either a “colored noise” or a random polyharmonic signal (Perez and Blanke, 2012; Fossen, 1994).

The wave model of the first type approximates the wave disturbance by the output of some low-pass shaping filter, fed by a white noise. This approach, prevailing in the literature, reduces roll stabilization control design to standard methods of optimal controller synthesis, such as the linear-quadratic Gaussian (LQG) control (van der Sluis, 1987; van Amerongen et al., 1990), $H_\infty$ control (Sharif et al., 1995; Blanke et al., 2000; Crossland, 2003; Stoustrup et al., 1994) and model-predictive control (MPC) (Perez, 2006). As usual in stochastic and minmax control, optimal controllers do not deliver optimal solutions for any specific realization of the stochastic disturbance, providing optimality either “on average” (in the sense of expectation) or in the “worst-case” scenario. Another downside of the mentioned methods is the necessity to estimate the spectral density of the wave motion.

An alternative “discrete” model of the wave motion, often used in marine engineering (Perez, 2006; Nicolau et al., 2005; Longuet-Higgins, 1963), approximates the wave motion by the sum of sinusoids with known frequencies, where the constant amplitudes are obtained via sampling of the spectral density and random phase shifts are uniformly distributed in $0,2\pi$ in order to get different realizations. For this model of the wave disturbance and linearized vessel’s yaw-roll dynamics, the optimal roll stabilization may be considered as a linear-quadratic optimization problem, where the control system is affected by a partially uncertain polyharmonic signal. A relevant extension of the classical LQR control to cope with such problems has been developed in (Yakubovich, 1995; Lindquist and Yakubovich, 1997, 1999; Proskurnikov and Yakubovich, 2006, 2012; Proskurnikov, 2015). It appears that (under natural assumptions) an optimal universal controller (OUC) exists, which is independent of the uncertain signal’s parameters, delivers the optimal process for arbitrary values of these parameters. Furthermore, the OUC can be found in the class of linear stabilizing controllers; a convenient parametrization of such OUCs has been found (Yakubovich, 1995).

In this paper, we apply Yakubovich’s theory of OUC to the problem of optimal roll stabilization. This paper extends our previous work (Kapitanyuk et al., 2016), which considered a simplified model of the vessel with a single rudder and no stabilizing fins. We illustrate the efficiency of OUCs in the optimal roll stabilization problem and compare it with classical controllers by using numerical simulations that utilize the “benchmark” vessel’s model from (Perez, 2006). The OUC theory provides a method for combined fin-rudder stabilization control design, avoiding the undesired counteraction between different actuators and improving the resulting efficiency of the control system. Unlike the usual LQR (Perez and Blanke, 2012), the OUC does need to measure the full state vector and provides optimality for any polyharmonic signal from the specified class; to find OUC, one does not need to solve the Riccati equation. Unlike LQG and $H_\infty$ approaches, the OUC design does not require one to know the spectral density of the wave motion (or, equivalently, the structure of the shaping filter). The OUC depends only on the fixed wave’s frequencies and ensures optimality of the cost functional for any realization of the random disturbance.

The paper is organized as follows. In Section 2, mathematical models of the vessel’s motion and wave disturbances are considered. In Section 3 the theory of OUC in general problems of linear-quadratic optimization with uncertain disturbances is introduced. In Section 4, we apply this theory to design an optimal roll stabilization controller, whose performance is studied numerically in Section 5.

2. Mathematical models

We first introduce mathematical models of the ship’s yaw-roll motion and the wave disturbances.

2.1. The vessel’s motion

The movements of a marine vessel (as a rigid body) have six degrees of freedom. The standard 6-DoF mathematical model can be found in (Perez and Blanke, 2012; Fossen, 1994). However, it is more convenient to use a simplified reduced-order model (van Amerongen et al., 1990; Fossen, 1994; Perez, 2006), which is derived (see details in Appendix A) under two simplifying assumptions: 1) the effects of the pitch and heave motion of the vessel on its surge, sway, roll and yaw dynamics are negligible; 2) the vessel’s speed is changing slowly relative to the remaining coordinates. Under these assumptions, the yaw and the roll controllers can be designed for a simplified linearized model.

In the original papers on rudder roll stabilization (Cowley and Lambert, 1972; Lloyd, 1975), the simplest configuration of the vessel with one rudder has been considered, whose angle is the single control input of the system. In general, the vessel can be equipped with multiple actuators (rudders, azimuth and tunnel thrusters, waterjets etc.); however, for the sake of autopilot and roll stabilization control design they are usually replaced by an equivalent “virtual rudder”, whose “angle” stands for the scaled rotating yaw moment, distributed among the actuators by a separate control allocation system (Johansen et al., 2008). In addition to this, we allow the vessel to have synchronized stabilizing fins, whose angle serves as the second control.

Denoting the rudder, the fin, the roll and the yaw (or heading) angles by, respectively, $\delta_\text{rud}$, $\delta_\text{fin}$, $\phi$ and $\psi$ (Fig. 1), the reduced-order vessel’s model has the structure illustrated in Fig. 2. The system is affected by the environmental disturbance, represented by its roll and yaw components $d_\phi$, $d_\psi$. The transfer functions from $\delta_\text{rud}$ and $\delta_\text{fin}$ to $\phi$ and $\psi$, denoted by $W_\phi s$, $W_\psi s$, and $W_\phi s$, $W_\psi s$ respectively, are as follows (Perez, 2006, Sect. 8.2)
where 

\[ \phi_f = \sum_{i=1}^{p} a_i^r \sin \omega_i t \phi_i^r, \]

\[ \phi_f = \sum_{i=1}^{p} a_i^q \sin \omega_i t \phi_i^q. \]

Here the spectrum \( \omega_1, \ldots, \omega_p \) is known. The special case \( p = 1 \) corresponds to the model of regular waves; however, a real state of the sea is best described by a random or irregular wave model. This stochastic process can be approximated by the model (3) with \( p \) being sufficiently large. The constant amplitudes \( a_i^r \) and \( a_i^q \) are obtained via sampling the spectral density with a small enough step \( \Delta \omega \) to ensure that the fundamental period of the finite sum of sinusoidal components is longer than the desired duration of the simulation. The random phase shifts \( \phi_i^r \) and \( \phi_i^q \) used to generate different realizations of the stochastic process are uniformly distributed in \( 0, 2\pi \). Although the model (3) of irregular waves can describe a sea state quite accurately, the direct use of it in the control design is difficult due to the high dimension. The better strategy is to consider a few “dominating” frequencies corresponding to the peaks of the spectral density. In general, the localization and the shape of the spectral density highly depend on many parameters of motion such as the average speed of the vessel, sailing conditions and a frequency response of the vessel’s hull; however, these “dominating” frequencies can be efficiently estimated in real time, see e.g. (Bellettet al., 2015; Bobtsov et al., 2012; Fedele and Ferrise, 2012; Hou, 2012) and references therein. For simplicity and clarity of presentation, we proceed to assume that the number and the values of such frequencies are known.

It should be noted that in the existing control literature the wave motion is usually approximated by the “colored noise”, that is, the output from a low-pass shaping filter fed by the white noise signal. The simplest approximation for the shaping filter’s transfer function (that is, the wave spectrum), is

\[ H(s) = \frac{K_s}{s^2} \frac{\sin(\tau s)}{\tau s}. \]

Here the constant \( K_s > 0 \) determines the wave strength, \( \omega_0 \) is the encounter frequency and \( \tau \) is the damping ratio (Perez and Blanke, 2012). Unlike our approach, using only the information about the frequencies, the existing approaches, as discussed in Introduction, typically use all parameters of the transfer function \( H(s) \), whose identification is a self-standing non-trivial problem. As discussed in (Perez and Blanke, 2012, Sect. 2.5), the shaping filter representation of the wave is primarily used in stochastic control, which is convenient for methods exploiting spectral factorization of the wave disturbance, while the more precise nonlinear multi-sine model is commonly used in naval architecture.

3. Linear-quadratic optimization in presence of uncertain polyharmonic signals

In this section, the basic ideas of the theory of OUC are given for the reader’s convenience, following the survey paper (Proskurnikov, 2015). The concept of universal controller dates back to early works on “signal invariance”, or disturbance decoupling in control systems, see e.g. the survey in Proskurnikov and Yakubovich (2003a, b).

We start with introducing some notation. The set of complex \( m \times n \) matrices is denoted by \( \mathbb{C}^{m\times n} \). The Hermitian complex-conjugate transpose of a matrix \( M \in \mathbb{C}^{m\times n} \) is denoted by \( M^* \in \mathbb{C}^{n\times m} \). We use \( \sqrt{1} \) to denote the imaginary unit. The real part of a number \( z \in \mathbb{C} \) is denoted by \( \Re z \).

3.1. A family of uncertain optimization problems

Consider a linear time-invariant optimization problem.
exogenous signal
\[ \dot{x} = Ax + Bu + Ed, \quad y = Cx + Du + Gd. \]
(5)

Here \( x \in \mathbb{R}^n, u \in \mathbb{R}^m, y \in \mathbb{R}^k \) stand for, respectively, the state vector, the control and the observed output. The signal \( d \in \mathbb{R}^l \) is a polyharmonic process with known spectrum \( \omega_1, \ldots, \omega_l \)

\[ d(t) = \text{Re} \sum_{j=1}^{N} d_j e^{i\omega_j t}, \]
(6)

whose complex amplitudes \( d_j \in \mathbb{C} \) (absorbing also the phase shifts) are uncertain. The components of this exogenous signal may include disturbances, measurement noises and reference signals.

In presence of the oscillatory disturbance (6), the solutions of (5) do not vanish at infinity. The goal of control is to guarantee boundedness of the solution \( x \cdot u \cdot t \) and its optimality in the sense of the following quadratic performance index

\[ J(x, u, d) = \min_{r=0}^{T} \int_{t_0}^{T} \mathcal{F}(x, u, d) dt. \]
(7)

Here \( \mathcal{F} \) is a quadratic form, which is assumed to be non-negative definite \( \mathcal{F} > 0 \). Considering the integrand in (7) as a measure of the solution’s “energy”, its average value \( J \) can be thought of as the solution’s “average power”. Formally, the control goal can be formulated as follows

\[ \text{minimize} \ J(x, u, d), \]
subject to \( 5 \) and \( \sup_{t \in [0, T]} |x(t) - x(0)| < \infty. \)
(8)

In fact, (8) defines an infinite family of optimization problems, corresponding to different choices of the amplitudes \( d_1, \ldots, d_k \). Obviously, the set of optimal processes also depends on the amplitudes and hence cannot be found explicitly. Nevertheless, it can be shown that an optimal universal controller (OUC) exists that provides an optimal process for any uncertain amplitudes \( d_j \), solving thus the whole family of optimization problems (8).

**Definition 1.** A causal operator \( \mathcal{H} : y \rightarrow u \) is an OUC for the family of optimization problems (8), if for any initial condition \( x(0) \in \mathbb{R}^n \) and any amplitudes \( d_1, \ldots, d_k \) in (6) there exists a unique solution of the closed-loop system

\[ \dot{x} = Ax + Bu + Ed, \quad y = Cx + Du + Gd, \quad u = \mathcal{H}(y), \]

which is bounded and delivers an optimum to (8).

### 3.2. A class of linear OUC

Although the existence of OUCs may seem exceptional, such controllers exist under rather mild assumptions on the system and the cost functional.

We assume that the system (3.1) is stable, that is, det \( sI - A \neq 0 \) whenever \( \text{Res} \). If the system is stabilizable and detectable, one may always augment it with an observer-based stabilizing controller, so the stability assumption can be adopted without loss of generality.

Let \( F, F^T \) stand for the matrix of the quadratic form \( \mathcal{F}(x, u, d) \) and \( F_0, F_0^T \) be the matrix of the quadratic form \( \mathcal{F}_0(x, u, d) \), that is

\[ \mathcal{F}(x, u, d) = \begin{bmatrix} x & u \end{bmatrix} \begin{bmatrix} A_x & B_x \\
F_x & F_u \end{bmatrix} \begin{bmatrix} x \\
u \end{bmatrix} + 2d^T F_dx + 2d^T F_{du} \phi + d^T F_{dd} \phi, \]
(9)

where \( F_{dx}, F_{du}, F_{dd} \) are matrices of appropriate dimensions. We introduce the rational complex-valued matrix \( \Pi_{\omega_0} \Pi_{\omega} \) as follows

\[ \Pi_{\omega_0} = \begin{bmatrix} A_{\omega_0} B_{\omega_0} \\
F_0 \end{bmatrix}, \quad \Pi_{\omega} = \begin{bmatrix} A_{\omega} B_{\omega} \\
F_\omega \end{bmatrix}, \quad \Pi_{\omega_0} = sI - A_{\omega_0} \]

and assume that the frequency-domain condition holds

\[ \Pi_{\omega} e^{sI} = \begin{bmatrix} 0 \end{bmatrix}, \quad \text{const} > 0. \]

For a similar discrete-time optimization problem, the proof is available in (Lindquist and Yakubovich, 1999), and the continuous-time case is considered in the same way.

Condition (10) is a standard solvability condition for classical LQR problems, providing the existence of the stabilizing solution to the Riccati equation (Anderson and Moore, 1990). It always holds when \( F_0, x, u \) is positively definite, which is a natural assumption in practice. The condition(10) cannot be discarded and, moreover, its “strong” violation in the sense that \( \Pi_{\omega_0} \Pi_{\omega} < 0 \) for some \( \omega_0 \in \mathbb{R} \) and \( \Pi_{\omega} \in \mathbb{C}^m \)

Under non-restrictive assumptions, the OUC exists and can be found among linear controllers

\[ N \frac{d}{dt} u = \begin{bmatrix} M \end{bmatrix} \frac{d}{dt} y, \]
(11)

where \( N \) and \( M \) stand for matrix polynomials; the matrix \( N s I \) is square and det \( N / 0 \). The relevant result is given by the following theorem.

**Theorem 1.** (Proskurnikov, 2015) Let the system (5) be stable and the inequality (10) hold. Then the linear controller (11) is an OUC for the family of problems (8) if the following two conditions hold

1. the closed-loop systems is stable, that is,

\[ \det \begin{bmatrix} sI - A \end{bmatrix} > 0, \quad \forall s \in \text{Res} \]

2. the closed-loop transfer function \( W_{ud} \) from \( d \) to \( u \) satisfies the interpolation equations

\[ W_{ud} \Pi_{\omega_0} R_1, \quad \forall j \in \{1, 2, \ldots, N\}, \]
(13)

where the constant matrices \( R_j \) are as follows

\[ R_j = \begin{bmatrix} \Pi_{\omega_0} \end{bmatrix}, \quad \Pi_{\omega_0} = \begin{bmatrix} A_{\omega_0} B_{\omega_0} \\
F_0 \end{bmatrix}, \quad \Pi_{\omega} = \begin{bmatrix} A_{\omega} B_{\omega} \\
F_\omega \end{bmatrix}, \quad \Pi_{\omega_0} = sI - A_{\omega_0} \]

Note that, unlike the classical LQR problem, where the optimal controller is uniquely defined from the Riccati equation, the OUC in the problem (8) is not unique; to find it, one need not solve Riccati equations. We will use Theorem 1 in a special situation, where \( \mathcal{F} \) depends only on the output and the control, i.e. \( F \) admits the decomposition

\[ F = \begin{bmatrix} C \end{bmatrix} \begin{bmatrix} D \\
G \end{bmatrix} \begin{bmatrix} F \end{bmatrix}, \quad \Pi_{\omega_0} = \begin{bmatrix} I_m \end{bmatrix}, \quad \Pi_{\omega} = \begin{bmatrix} I_l \end{bmatrix}, \]
(14)

where \( \begin{bmatrix} F \end{bmatrix} \) is a matrix of appropriate dimensions. In this situation, one has

\[ \Pi_{\omega_0} = \begin{bmatrix} W_{sE} \Pi_{\omega} \\
\Pi_{\omega} \end{bmatrix}, \quad \Pi_{\omega} = \begin{bmatrix} W_{sE} \Pi_{\omega} \\
\Pi_{\omega} \end{bmatrix}, \quad \Pi_{\omega_0} = sI - A_{\omega_0} \]
(15)
Here \( W_{ou}^0 \), \( s \) and \( W_{ou}^1 \), \( s \) stand for the open-loop transfer functions from respectively \( u \) and \( d \) to \( y \)
\[
W_{ou}^0 : CA_1^1B, \quad W_{ou}^1 : CA_1^1E, \quad G.
\]

Recalling that \( A \) is a Hurwitz matrix, it can be shown that the closed-loop system is stabilized by the controller (11), whose coefficients are as follows
\[
\begin{align*}
M s & \quad \Delta s = r s, \\
N s & \quad M s = CA_1^1B, \quad D s \quad \rho = \rho = I_n, \\
\Delta s & \quad : \det A, \quad \det sI_n, \quad A.
\end{align*}
\]

Here \( r s \) is a matrix polynomial and \( \rho s \) is a scalar Hurwitz polynomial with \( \deg \rho = \deg M \). Such a controller is “feasible” in the sense that its transfer matrix \( N^{-1}M \), as well as the closed-loop system’s transfer matrices from \( d \) to \( x, u, \) are proper. For the controller (11), (16), one obtains
\[
W_{ol} s = \frac{M s}{\rho s} W_{ou}^0 s,
\]
and the interpolation constraints (13) boil down to
\[
\Delta s \omega_j, \quad \Delta s \omega_j, \quad \rho s \omega_j, \quad \rho s \omega_j, \quad R_j.
\]

The constraints (18) can be satisfied when
\[
\det \left[ W_{ou}^0 \omega_j, W_{ou}^1 \omega_j \right] / 0 \forall j \quad 1, \ldots, N.
\]

Here \( W_{ol}^0 \) is the open-loop transfer matrix from \( d \) to \( y \). The conditions (19) typically hold when \( \text{dimg} \) \( \text{dimd} \). Furthermore, if (19) holds, the coefficients of \( r \) and \( \rho \) can be chosen as continuous functions of \( \omega_j \), so that the controller is robust to small deviations in the spectrum \( \omega_j \) \( \omega_j \). Choosing an arbitrary Hurwitz polynomial \( \rho \) of degree \( \deg \rho \) \( 2N \) \( \deg \rho \) \( 1 \), one needs to find the matrix polynomial \( r \) with \( \deg r \) \( 2N \) \( 1 \), satisfying the conditions
\[
r \omega_j, \quad \rho \omega_j, \quad \rho \omega_j, \quad \rho \omega_j, \quad R_j.
\]

Separating the real and imaginary parts, one obtains \( 2N \) equations for \( 2N \) real coefficients of \( r \).

It appears that any OUC (11) is equivalent, in some sense (Yakubovich, 1995; Proskurnikov, 2015), to the controller (16) with some polynomials \( r, \rho \), satisfying the interpolation constraints (18).

**Remark 1.** Note that the controller (16) in fact does not depend on the state-space model (5), involving only the system’s characteristic polynomial \( \Delta s \) and the open-loop transfer function \( W_{ou}^0 s : D C s I A_1^1B \) from \( u \) to \( y \) (Fig. 3). In the case where \( \frac{\Delta s}{\Delta s} y, u \) depends only on \( y \) and \( u \), the interpolation conditions (18) also involve only the values of \( W_{ou}^0 \omega_j \) and \( W_{ou}^1 \omega_j \) rather than the whole state model (5). Hence, in this special situation, the design of OUC requires only the knowledge of \( \Delta s \), \( W_{ou}^0 s \) and \( W_{ou}^1 s \), which are independent of the minimal state-space realization.

**Remark 2.** In general, one has a lot of freedom in choosing the coefficients of \( \rho s \), and their “optimal” choice remains an important research topic as a subject of ongoing research. In practice, the polyharmonic model of the disturbance is usually imprecise: the signal \( d \) \( t \) contains frequencies other than \( \omega_j \) (whose amplitudes are sufficiently small). Fig. 3 suggests that, ideally, the OUC’s transfer function \( r s / \Delta s \) should have a sufficiently narrow bandpass, containing the frequencies \( \omega_j \) in order to damp these unmodeled spectrum. Although this requirement is not very formal, it can be used for practical tuning of the OUC’s parameters.

**Remark 3.** As discussed in (Lindquist and Yakubovich, 1999), the important property of the OUC (11) is its robustness against small changes in the frequencies \( \omega_j \), whereas the straightforward LQR-based design leads to a controller that is formally optimal yet non-robust to deviations in spectrum. The results from (Lindquist and Yakubovich, 1999) deal with discrete-time systems, but this robustness property is retained by the continuous-time OUC (11).

4. Optimal universal roll stabilization controllers

In this section, we reduce the optimal roll stabilization problem to a special case of the problem (8). The cost functional will depend only on the control effort and output. In view of Remark 1, in this situation one does not need to know a special state-space representation of the open-loop system, requiring only its characteristic polynomial and transfer matrices \( W_{ou}^0, W_{ou}^1 \). In this sense, an optimal controller can be designed in the frequency domain.

We assume that the vessel’s heading is stabilized by a known autopilot (Fig. 4). Behind this statement, there are two practical considerations. First of all, it allows splitting of the adjustment procedure for a motion control system on the vessel in two sequential stages: the independent tuning of an autopilot and the following design of the roll stabilization controller. The second reason is the flexibility and the modularity; the roll stabilization system may be supplied by a manufacturer of the equipment such as high-performance rudders or active fins independent of the development of the autopilot, which is in itself a challenging task. The autopilot design problem has been thoroughly

![Fig. 3. The structure of the OUC (16).](image-url)
studied in the literature [Fossen, 1994; Perez, 2006; Nicolau et al., 2005; Veremey, 2014] and is beyond the scope of this paper. Furthermore, we assume that the roll stabilization system is aware of the measured heading of the vessel and the constant heading setpoint ψ. In practice, ψ t can be a function of time, e.g., when autopilot steers the vessel along a curvilinear path. However, these dynamics are much slower than the ship’s roll motion, and hence are neglected in the roll stabilization system design. The deviation among them (heading error) eψ t along with the roll stabilization error eθ t are the inputs to the roll stabilization system (Fig. 4). Mathematically,

\[ e_\theta t : \psi t \rightarrow \delta t \rightarrow \varphi t, \quad e_\psi t : \phi t \rightarrow \phi t \]

The rudder angle δθ is the sum of the autopilot’s and the roll stabilization controller’s commands (Fig. 4), denoted respectively by δθ t and u1 t. The fin angle δu t is used as the second control input u2 t. Denoting the autopilot’s transfer function by \( W_{\phi \theta} \), one has

\[ \delta_{\text{roll}} = \delta_{\theta} + \delta_{\psi}, \quad \delta_{\text{fin}} = u_1 t . \]

The yaw-roll dynamics of the vessel, closed by the autopilot, are represented by the input-output model

\[ y t : W_{\psi \psi}^0 \frac{d}{dt} u t \rightarrow W_{\psi \theta}^0 \frac{d}{dt} \frac{d}{dt} t, \]
\[ y t : \begin{bmatrix} e_\theta t \\ e_\psi t \end{bmatrix}, u t : \begin{bmatrix} u_1 t \\ u_2 t \end{bmatrix}, d t : \begin{bmatrix} \varphi t \\ d_\psi t \end{bmatrix} . \quad (21) \]

Here \( d_\psi t, d_\theta t \) are the polyharmonic components of the wave-induced motion (3). Considering \( \varphi \) as a harmonic signal of zero frequency, \( d t \) is a special case of (6) with \( l = 3, N = 1, p \), where \( \omega_1, k_1, \ldots, k_p \) are the wave frequencies from (6) and \( \omega_0, \rho_0 \) are the transfer functions \( W_{\phi \psi}^0, W_{\phi \theta}^0 \) depend on the autopilot’s transfer function \( W_{\phi \psi} \) from \( e_\psi \) to \( \delta_\psi \) and the functions \( W_{\theta \psi}, W_{\theta \theta} \) from (1). The exact formulas for \( W_{\phi \psi}^0, W_{\phi \theta}^0 \) are derived in Appendix B and it can be easily seen from these formulas that (19) always holds for any wave \( \omega_1, \ldots, \omega_6 \). The cost functional penalizes the mean square values of the following three variables.

(i) the roll displacement \( e_\psi \),
(ii) the heading deviation \( e_\theta \), and
(iii) the control effort.

Denoting the corresponding penalty weights by \( a, b, c > 0 \), we introduce the quadratic cost functional as follows

\[ J = \lim_{T \rightarrow \infty} \int_0^T \mathcal{J} y t, u t, d t, \quad (22) \]

\[ \mathcal{J} y, u : a e_\psi^2 + b e_\theta^2 + c \gamma_1 u_1^2 + \gamma_2 u_2^2 . \]

The Hermitian form \( \mathcal{J} \) can be represented in the form (14), where \( \mathbf{F} \) is defined by

\[ \mathbf{F} = \begin{pmatrix} a & 0 & 0 & 0 \\ 0 & b & 0 & 0 \\ 0 & 0 & c & 0 \\ 0 & 0 & 0 & c \end{pmatrix} . \]

The matrix function \( W_0 i \) and the matrices \( R_i \) are defined by (15); \( \Pi i W_0 \) is the transfer function of the stabilizer system with the coefficients that satisfy (18). By fixing \( p, a_0, a_1, \ldots, a_p, \beta_0, \beta_1, \ldots, \beta_p \) and splitting the real and imaginary parts in the interpolation condition (18), one obtains a pair of real-valued matrix equations for the coefficients of \( r s \). The only exception is \( j N p = 1 \), since \( a_0 = 0 \), equation (18) is real-valued. Hence we get 2 equations for the coefficients of the polynomial \( r s \). To satisfy them, the polynomial \( r s \) should have 2 real-valued coefficients, i.e., it suffices to choose \( degr + deg_\theta \) of \( \deg_\Delta \).

The just described algorithm to design an OUC for the roll stabilization problem can be summarized as follows:

1. Choose a Hurwitz polynomial \( \rho s \) with \( degr + 2p \) \( deg_\theta \);
2. Compute the matrices \( R_i \) from (15) (here \( N = 1, p, a_0, a_1, \ldots, a_p \) are the frequency components from (3) and \( aN = a_0, a_1, \ldots, a_p \) - 0);  
3. Compute \( W_{\phi \psi}^0, W_{\phi \theta}^0 \) (see Appendix B);
4. Find the real coefficients of the matrix polynomial \( r s \) \( r_0, \ldots, r_{2p+2p} \) from (20);
5. The controller (11) with the coefficients (16) provides optimality of (22) for any uncertain amplitudes and phases.

For the detailed derivation of the OUC controller one may represent the transfer functions (1) as follows

\[ W_{\phi \psi} s = \frac{b_{\phi \psi} s}{a s}, \quad W_{\phi \theta} s = \frac{b_{\phi \theta} s}{a s}, \quad (23) \]

\[ W_{\phi \psi}^0 s = \frac{b_{\phi \psi}^0 s}{a s}, \quad W_{\phi \theta}^0 s = \frac{b_{\phi \theta}^0 s}{a s}, \quad (24) \]

A straightforward computation of \( W_{\phi \psi}^0 s, W_{\phi \theta}^0 s \) (see Appendix B) shows that

\[ W_{\phi \psi}^0 s = \frac{1}{\Delta s} \begin{bmatrix} \Delta s \frac{a s b_{\phi \psi} s}{a s} & \frac{b_{\phi \psi}^0 s}{a s} \\ \frac{b_{\phi \psi}^0 s}{a s} & \frac{b_{\phi \psi} s}{a s} \end{bmatrix}, \]
\[ W_{\phi \theta}^0 s = \frac{1}{\Delta s} \begin{bmatrix} \Delta s \frac{a s b_{\phi \theta} s}{a s} & \frac{b_{\phi \theta}^0 s}{a s} \\ \frac{b_{\phi \theta}^0 s}{a s} & \frac{b_{\phi \theta} s}{a s} \end{bmatrix} . \]

\[ \Delta s \begin{bmatrix} a s b_{\phi \psi} s & b_{\phi \psi} s & b_{\phi \psi}^0 s \end{bmatrix}, \quad \Delta s \begin{bmatrix} \frac{b_{\phi \psi}^0 s}{a s} & \frac{b_{\phi \psi} s}{a s} \end{bmatrix} . \]

Obviously, \( degr + deg_\theta \) are the coefficients of a specific vessel’s model is illustrated in the next section.

5. Numerical simulation

In this section we consider a numerical example to illustrate the proposed approach.

5.1. Vessel’s motion and wave disturbance

To design the linear controllers, we consider the vessel’s 4-DOF (surge, sway, roll and yaw) model from (Perez, 2006; Appendix B). This maneuvering model of a multipurpose naval vessel is implemented
in the Marine Systems Simulator (MSS) Toolbox (Fossen and Perez, 2004) and is used in our numerical simulations. The vessel has one rudder and two synchronous fins. Linearizing the model at the speed 8 m/s, the coefficients of the transfer functions (23) are as follows (Perez, 2006; Appendix B)

\[
\begin{align*}
    a_{ss} & = 0.4375 s + 0.04404 s^2 + 0.2164 s + 1.31, \\
    b_{uu_s} & = 0.159 s + 0.4919 s + 0.3005, \\
    b_{uv} & = 0.078 s + 0.1785 s^2 + 0.2586 s + 1.324, \\
    b_{wy} & = 0.402 s + 0.4501 s + 0.03056, \\
    b_{wv} & = 0.006 s + 0.9642 s^2 + 0.1974 s + 0.2361.
\end{align*}
\]

For this simulation we assume that the stabilizing autopilot (24) has the following form

\[
a_{ap} s + 10, \quad b_{ap} s + 57 s + 0.5263.
\]

Whereas the controller design is based on this linearized model, our simulations take into account the nonlinear dynamics of the rudder’s and fins’ steering machines (Perez, 2006, 5.6) with the maximal angles 40 (rudder) and 35 (fins) and the maximal rates 5 /s and 25 /s respectively. (Perez, 2006; Appendix B.4).

To cope with saturations, we use the heuristical approach, called the automatic gain control (AGC) (van der Klugt, 1987; Lauvdal and Fossen, 1998) that decreases the actuator command in a smart way to ensure that saturation (of the actuator angle or rate) never occurs. In Fig. 5 we compare the commands from our OUC (whose design will be specified in Subsection 5.3) before and after the AGC algorithm. The rudder is not saturated, in this case the command remains unchanged. The fin angle’s saturation is prevented by AGC.

To obtain the proper time series of the polyharmonic approximation of the irregular wave (3) we use the methodology presented in (Perez and Blanke, 2012, Sec. 4.2.5). The resulting realization is obtained for the long-crested irregular sea in beam seas. The response amplitude operator has been taken from (Perez and Blanke, 2012, Table B9.), where the number of sinusoidal components is 1000. We consider the JONSWAP spectrum (Fossen, 1994, Section 4.2.1), which is characterized by two parameters: the significant wave height and the peak value of the spectrum (peak frequency). We consider two different significant wave heights (1.5 m and 3 m) and three different peak values (1.15 rad/s, 0.8 rad/s, 0.5 rad/s). Also, we compare the controllers’ behavior at three different speeds: 8 m/s (the linearization point of the model at which the controller is designed), 5 m/s (medium speed) and 1 m/s (low speed at which the rudders and fins are limited with small inflow velocity). In total, we consider 6 different scenarios (Table 1). The power spectra are shown in Fig. 6a–d.

We use “rough” approximations of the signal (3) taking only one “dominating” sinusoidal component. For the frequencies of the sinusoidal signal, we choose \( \omega_1 = 1.15 \) rad/s and \( \omega_2 = 0.5 \) rad/s. To evaluate the robustness of OUC against unspecified harmonics, in Case 6 we consider the peak frequency 0.8 rad/s which is different from \( \omega_1 \) and \( \omega_2 \).

### 5.2. The standard controllers

We compare the OUC with two other types of linear controllers. The first of these controllers is the classical LQR controller (Fossen, 1994; Appendix D), designed to optimize the cost function

\[
J_{LQR} = \int_0^\infty \alpha \omega^2 + \beta \dot{\omega}^2 + \gamma_1 \dot{\psi}^2 + \gamma_2 \dot{\psi}^2 \, dt.
\]

in the absence of disturbances. We choose the parameters \( \alpha = 5, \beta = 1, \gamma_1 = 0.01, \gamma_2 = 0.001. \)

The conventional loop shaping controller (van Amerongen et al., 1990) has been chosen as another algorithm for comparison. This method ignores the yaw dynamics, working directly with the transfer function \( W_{\theta \psi} \) (see Appendix B). For the known dominating frequency of the disturbance, we select the structure of the notch filter centered at that point to damp the frequencies around it. The controller takes the following form

\[
W_c \left( s \right) = \frac{\omega_1 s - \dot{\psi}}{\omega_3 s} \left( \frac{0.2 \left( 1.15 \right)^2}{s} \right) \left( \frac{1.15}{\sqrt{2}} \right).
\]

### 5.3. The OUC design

The coefficients of the cost functional (22) are chosen as \( \alpha = 5, \beta = 1, \gamma_1 = 10 \) and \( \gamma_2 = 2. \) It should be noted that, in spite of similar cost functions, the behaviors of the two controllers are very different. Actually, the cost function (25) is in principle finite only for the disturbances vanishing as \( t \to \infty, \) and its optimality for \( d = 0 \) does not guarantee any optimal performance for the polyharmonic disturbance. For this reason, the choice of the coefficients \( \alpha, \beta, \gamma_1, \gamma_2 \) is a delicate issue. We have tuned them in such a way that the LQR and OUC provide (approximately) same quality of course keeping (see the heading errors in Table 3).

In the design procedure from the previous section, we should choose

---

![Fig. 5. Commands for the rudder (not saturated in the experiment) and fin angle (saturation prevented by AGC).](image-url)
the Hurwitz polynomial of the order \( \deg \rho > \deg \Delta + 2p \). 10. The polynomial \( \rho(s) \) is chosen as follows

\[
\rho(s) = \Delta_{\text{LQR}}(s)(s + \eta) s^2 + 2\xi \omega_1 s + \omega_1^2 s^2 + 2\xi \omega_2 s + \omega_2^2 \quad \text{.} 
\]  

(26)

Here \( \omega_0 = 0, \omega_1 = 0.5, \omega_2 = 1.15 \) are the frequencies of the wave disturbance, \( \xi = 1/\sqrt{2}, \eta = 2 \) and

\[
\Delta_{\text{LQR}}(s) = s^6 + 17.2s^5 + 101.3s^4 + 300.1s^3 + 201.3s^2 + 52s + 5 \quad \text{.}
\]

is the characteristic polynomial of the closed-loop system, which corresponds to the LQR controller described above. The reasons to choose this polynomial are discussed below in Subsection 5.5.

### 5.4. Simulation results

Figs. 7–13 the results of simulation in Cases 1–6 are presented. The simulation time is 500s, in Figs. 7–12 we zoom the time window

Fig. 11. The result of simulation in Case 5: roll angle $\epsilon_1$, heading error $\epsilon_2$, rudder and fin angles ($u_1, u_2$).
400–500s in order to simplify viewing. Fig. 13 shows the dynamics of roll angle for all 6 cases over the whole period of 500s. As has been mentioned, we always combine the controllers with the AGC algorithm.

The standard deviations of roll angle and heading errors are summarized in Tables 2, 3 respectively.

Notice that in Case 3 (the speed is too small) all controllers are equally inefficient since the performance of rudders and fins is very limited. In all other cases, OUC demonstrates smaller average roll than the remaining controllers providing a comparable yaw error. Notice that this also holds in Case 6, although the actual peak frequency of the signal is different from the nominal frequencies of the wave disturbances \( \omega_1, \omega_2 \). The main disadvantage of the LQR is the lack of knowledge about the structure of the disturbance signal. The LQR controller shows better performance than loop shaping in Cases 1–4, because it efficiently damps the ship roll natural (resonance) frequency of the vessel (Perez and Blanke, 2012) (1.1s), which is very close to the peak frequency of the wave disturbance. In Cases 5 and 6, the significant energy of the spectrum is beyond the vicinity of resonance frequency, for this reason, the performance of the simple loop-shaping controller is better.

5.5. Choice of the polynomial \( \rho s \) and its influence on the closed-loop system

Mathematically, every choice of the scalar polynomial \( \rho s \) is feasible (provided that it has a sufficiently large degree and is Hurwitz). In practice, its choice influences the characteristics of the closed-loop system since the closed-loop transfer functions from the disturbance to the, respectively, control and the output are

\[
W_{sd} s = \frac{\rho s}{\rho s} - W_{sd} s W_{in} s W_{sd} s W_{sd} s .
\]

Here \( W_{in} \) \( D \) \( CA_1 B \) and \( W_{sd} \) \( G \) \( CA_1 E \) are the stable open-loop transfer functions, independent of the choice of the controller. Hence, the choice of the \( \rho s \) determines, first, the stable poles of the closed-loop system and, second, its frequency-domain characteristics. The interpolation conditions provide optimal attenuation of the spectrum in a small vicinity of the nominal frequencies \( \omega_1, \omega_2 \). As stated in Remark 2, attenuation of the disturbance frequencies beyond this vicinity is most critical for the overall system performance.

The influence of \( \rho s \) on the closed-loop system is illustrated in Fig. 14. The latter figure shows the magnitude Bode plots of the functions \( W_{rd} \) and \( W_{ad} \) (the influence of roll disturbance on the roll angle and rudder angle), corresponding to the polynomial \( \rho s \) with \( \rho = 1 \) (26) and \( \tau = 0.8 \). Here \( \tau \) plays the role of the system’s sensitivity. The empirical observation shows that, as one decreases \( \tau \) (the system becomes “slower”, or less sensitive), the performance with respect to roll angle deteriorates (in particular, the roll angle becomes wider), whereas increase in \( \tau \) leads to better stabilization. At the same time, large values of \( \tau \) correspond to excessive use of the actuators, whereas smaller values of \( \tau \) make their dynamics more smooth.

The “optimal” assignment of closed-loop system’s poles and shaping the transfer functions of the closed-loop system are long-standing problems in control theory (Franklin et al., 1981). The denominator \( \rho s \) of the closed-loop transfer function \( W_{sd} s \) can be decomposed into the product

\[
\rho s \sum_j 1 \ T_j s \sum_j s^2 2 \zeta_j \omega_{nj} s \omega_{nj}^2 ,
\]

where \( \omega_{nj} \) are the so-called natural frequencies, \( \zeta_j \) are called damping ratios and \( T_j \) are called time constants (Franklin et al., 1981, Chapter 6). Unlike the classical situation, the numerator of the transfer function depends on \( \rho s \) due to the interpolation constraints (19); also, the order of this transfer function (deg \( \rho \)) has to be sufficiently large in order to

![Fig. 12. The result of simulation in Case 6: roll angle \( \eta_1 \), heading error \( \eta_2 \), rudder and fin angles \( (u_1, u_2) \).](image-url)
satisfy the interpolation constraints. In spite of this, the standard recommendations on the pole placement (Franklin et al., 1981), applied to the choice of $\rho_s$, give a satisfactory result, as demonstrated by simulations in Section 5.4. One of these recommendations is to place the poles of the closed-loop system by using a standard LQR procedure. Since we are comparing our controller’s behaviors with a specified LQR controller, it is natural to assign the corresponding closed-loop system’s poles (zeros of $\Delta_{LQR}$) to be the roots of $\rho_s$. To attenuate frequencies
beyond $\omega_1$, $\omega_2$ and $\omega_3$, we also include the two Butterworth polynomials $\tau = \sqrt{2} \omega_1 a_1^2$, $\tau = \sqrt{2} \omega_2 a_2^2$ and an additional multiplexer 1 $T_s$. The value of $T_s = 0.5$ is chosen in order to provide the attenuation of the disturbance in the frequency band 0.22 rad/s, which contains 93% of the roll disturbance energy. Also, we renormalize $\rho \tau$ to set its leading coefficient to 1. This leads us to the polynomial $\rho \tau$ from (26).

6. Conclusions and future work

In this paper, we offer a novel approach to the design of the roll stabilization system for marine vessels, based on the idea of optimal universal controllers (OUC). Unlike the existing approaches, such a controller does not require the full information about the wave’s spectral density, but only the knowledge of its dominant frequencies. A topic of ongoing research is to employ adaptive control methods to enable the controller’s functioning in the fully uncertain environment. In particular, combining the roll stabilization controller with an estimator of the dominating encounter wave frequencies (Bobtsov et al., 2012; Belletter et al., 2015), one can adjust the coefficients of the OUC controller “on the fly”.

In our simulations, the OUC has been enhanced by an automatic gain controller (AGC) (van Amerongen et al., 1990; van der Klugt, 1987) preventing saturation of actuators. It could also be used with alternative gain scheduling techniques, e.g. time-varying gain reduction (Lauvdal and Fossen, 1998) or, more generally, advanced control allocation methods taking into account nonlinear dynamics of actuators (Zaccarian, 2009; Johansen and Fossen, 2013). Mathematical analysis of the resulting nonlinear systems remains, however, a non-trivial problem for future research.

Another limitation that can be relaxed is the fixed cruising speed of the vessel (determining the point of linearization, see Appendix A). Our simulation (Section 5.3) shows that the OUC controller is quite robust to the change of speed, although the optimality of the cost function is no longer guaranteed. For vessel’s maneuvers at a non-constant speed, more sophisticated controllers can be designed that are based on the paradigm of gain scheduling (Rugh and Shamma, 2000). Note however that the choice of a specific procedure allowing to redesign a linear fixed-speed controller into a nonlinear controller, applicable for non-constant speed, remains a non-trivial open problem. Also, such a redesign should be applied not only to RRS system, but also to the ship’s autopilot.

Appendix A. Linearized 4-DoF vessel motion model

A ship in a seaway moves in 6-DoF: three translation displacements (surge, sway and heave) define the location and three angular displacements (roll, pitch and yaw) define the attitude. In traditional maneuvering problems (such as e.g. course-keeping), normally a 3-DoF model (surge-sway-yaw) is considered. However, to consider the roll stabilization problem, one needs a 4-DoF model that includes the roll motion. In this paper, we use the Christensen and Blanken model (Fossen, 1994, Section 9.1.3). The following equations of motion are valid when the body-fixed axes correspond to the longitudinal, lateral and normal directions:

$$
\begin{align*}
&\left[\begin{array}{c}
\dot{u} \\
\dot{v} \\
\dot{\theta}_b \\
\dot{\phi}_b \\
\dot{\psi}_b \\
\dot{\psi}_v
\end{array}\right] = \\
&\begin{bmatrix}
m & m_{yv} & m_{yv} & m_{yv} & p & m_{yv} & m_{yv} & m_{yv}

& m_{yv} & m_{yv} & m_{yv} & m_{yv} & m_{yv} & m_{yv} & m_{yv}

& m_{yv} & m_{yv} & m_{yv} & m_{yv} & m_{yv} & m_{yv} & m_{yv}

& m_{yv} & m_{yv} & m_{yv} & m_{yv} & m_{yv} & m_{yv} & m_{yv}

& m_{yv} & m_{yv} & m_{yv} & m_{yv} & m_{yv} & m_{yv} & m_{yv}

& m_{yv} & m_{yv} & m_{yv} & m_{yv} & m_{yv} & m_{yv} & m_{yv}
\end{bmatrix}
\begin{bmatrix}
u \\
r \\
\psi_v \\
\psi_v \\
\psi_v \\
\psi_v
\end{bmatrix}

&+ \begin{bmatrix}
t_{suv} & t_{sv} & t_{sv} & t_{sv} & t_{sv} & t_{sv} & t_{sv}

&t_{sv} & t_{sv} & t_{sv} & t_{sv} & t_{sv} & t_{sv} & t_{sv}

&t_{sv} & t_{sv} & t_{sv} & t_{sv} & t_{sv} & t_{sv} & t_{sv}

&t_{sv} & t_{sv} & t_{sv} & t_{sv} & t_{sv} & t_{sv} & t_{sv}

&t_{sv} & t_{sv} & t_{sv} & t_{sv} & t_{sv} & t_{sv} & t_{sv}

&t_{sv} & t_{sv} & t_{sv} & t_{sv} & t_{sv} & t_{sv} & t_{sv}
\end{bmatrix}
\begin{bmatrix}
\tau \\
\tau \\
\tau \\
\tau \\
\tau \\
\tau
\end{bmatrix}

\end{align*}
$$

where $m$ is the mass of the ship; $x_u$, $y_v$ and $z_w$ are the coordinates of the ship’s center of gravity with respect to the body frame; $u$ and $v$ are the surge and sway velocities; $p$ and $r$ are the roll and yaw rates. The total vector of forces $\tau$ given with respect to the body frame can be decomposed as

$$
\begin{align*}
\tau &= \tau_u + \tau_v + \tau_w + \tau_p + \tau_r
\end{align*}
$$
where $\tau_{hyd}^p$, $\tau_{hyd}^c$ and $\tau_{hyd}^r$ stand for hydrodynamic, hydrostatic, actuators (fins and rudders) and propulsion forces and moments respectively.

It is usually assumed that the propulsion forces are compensated by the hydrodynamic resistance of the ship’s hull $\tau_{hyd}^h = 0$ and the surge acceleration is very small, that is, $\ddot{u} = 0$ and $u = U$, where $U$ is the service speed of the vessel. This leads to a simplified model to the following form:

$$
\begin{aligned}
\dot{x} &= M^{-1} f_x + M^{-1} c_x \\
\dot{y} &= M^{-1} f_y + M^{-1} c_y
\end{aligned}
$$

(A.1)

where, by definition,

$$
M = 
\begin{bmatrix}
\begin{array}{cccc}
\ell & \ell & \ell & \ell \\
\ell & \ell & \ell & \ell \\
0 & 0 & 0 & 1 \\
0 & 0 & 0 & 1
\end{array}
\end{bmatrix}
$$

where $\psi$ is the roll angle, $\psi$ is the yaw angle; $Y_i$, $K_i$ and $N_i$ stand for the hydrodynamic derivative (Perez, 2006) of the sway force, roll moment and yaw moment with respect to $\dot{i}$, $\dot{v}, \dot{p}, \dot{r}$ term; $\tau_{sway}^h$, $\tau_{roll}^h$ and $\tau_{yaw}^h$ are the nonlinear hydrodynamic forces that are found from

$$
\begin{aligned}
\tau_{sway}^h & = Y_{sway}(U)|v| \sqrt{v^2} \\
\tau_{roll}^h & = K_{roll}(U)|r| \sqrt{r^2} \\
\tau_{yaw}^h & = N_{yaw}(U)|\psi| \sqrt{\psi^2}
\end{aligned}
$$

where $\rho$ is the water density, $g$ is the acceleration of free fall, $GZ\, \psi$ is the so-called roll righting arm (Perez, 2006), and $\nabla$ is the displaced volume.

Assuming that the changes of roll and yaw angles are small one can linearize the model (A.1) around the equilibrium point $v = 0, p = 0, r = 0, \psi = 0, \theta = 0$ and $\phi = U$, i.e. the vessel is moving straight with the constant speed. That bring us to the following linear model:

$$
\begin{aligned}
\dot{x} &= Ax + B \tau_{r}^c \\
\dot{y} &= Cs + Gd \tau_{r}^c
\end{aligned}
$$

where the coefficients are found from (A.2) and

$$
\begin{aligned}
\begin{bmatrix}
x' \\
y'
\end{bmatrix} &=
\begin{bmatrix}
1 & \sin \xi \\
0 & 2f_x/L_x
\end{bmatrix}
\begin{bmatrix}
\delta_{roll} \\
\delta_{fin}
\end{bmatrix}
\end{aligned}
$$

where

$$
\begin{aligned}
L_x &= \frac{1}{2} \rho \ell \frac{\partial C_L}{\partial \delta_{roll}} \\
L_y &= \frac{1}{2} \rho \ell \frac{\partial C_L}{\partial \delta_{fin}}
\end{aligned}
$$

are the resulting hydrodynamic forces induced on the rudder and the fins respectively; $\ell_x, \ell_y$ are respectively the longitudinal and vertical distances from the center of gravity (CG) to the rudder, $\xi$ is the fins tilt angle defined in the aft view, $\ell_x$ is the fin roll arm, $\ell_y$ is a longitudinal distance from the CG
to the fin’s center of pressure; $C_L_{\text{rud}}$ and $C_L_{\text{fin}}$ are the lift characteristics for the rudder and fins respectively, $A_r$ and $A_f$ stand for to the rudder and fins areas.

$$
\begin{align*}
A &= M \begin{bmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}, \\
B &= M \begin{bmatrix} 1 \\ 0 \\ 1 \\ 0 \end{bmatrix}, \\
C &= \begin{bmatrix} Y_{\psi U} U & 0 & Y_{\psi r} m U & Y_{\psi U^2} \end{bmatrix}, \\
G &= \begin{bmatrix} Y_{\psi U} U & 0 & Y_{\psi r} m U & Y_{\psi U^2} \end{bmatrix}.
\end{align*}
$$

(A.2)

### Appendix B. Transfer matrices of the ship-autopilot system

In this section we are going to present the transformation procedure on how to obtain the models in equation (21) based on the general dynamics of the vessel described by the transfer function

$$
\begin{align*}
\phi t &= W_{\phi t} \frac{d \phi}{dt} + W_{\phi f} \frac{d \phi f}{dt} + \delta_{\text{rud}} t, \\
\psi t &= W_{\psi t} \frac{d \psi}{dt} + W_{\psi f} \frac{d \psi f}{dt} + \delta_{\text{fin}} t.
\end{align*}
$$

The observed outputs of the system are

$$
\begin{align*}
e_{\phi t} &= \psi t - d_{\phi t} t - \overline{\psi}, \\
e_{\psi t} &= \phi t - d_{\phi t} t,
\end{align*}
$$

where $\overline{\psi}$ is the heading setpoint. We introduce the two control inputs as follows

$$
\begin{align*}
u_1 &= \delta_{\text{rud}} t, \\
u_2 &= \delta_{\text{fin}} t,
\end{align*}
$$

where $W_{\text{AP}}$ is the autopilot’s transfer function, stabilizing the vessel’s yaw motion. Putting the equations together, one arrives at the following

$$
\begin{align*}
1 & \quad W_{\phi t} W_{\phi t} & e_{\phi} & W_{\phi t} W_{\phi f} & u_1 \\
0 & \quad W_{\psi t} W_{\psi t} & e_{\psi} & W_{\psi t} W_{\psi f} & u_2 \\
0 & \quad 1 & 0 & 1 & \frac{\overline{\psi}}{d_{\phi}}, \\
1 & \quad 0 & 1 & 0 & \frac{d_{\phi}}{d_{\psi}}.
\end{align*}
$$

Assuming that the autopilot stabilizes the yaw loop i.e. $1 \quad W_{\psi t} W_{\psi t} / 0$ this yields

$$
\begin{align*}
e_{\phi} &= \begin{bmatrix} W_{\phi t} W_{\phi t} \\ W_{\phi t} W_{\phi f} \end{bmatrix} u_1, \\
e_{\psi} &= \begin{bmatrix} W_{\psi t} W_{\psi t} \\ W_{\psi t} W_{\psi f} \end{bmatrix} u_2, \\
\begin{bmatrix} W_{\overline{\psi}} \\ W_{\overline{\psi}} \end{bmatrix} W_{\phi f} W_{\phi f} & d_{\phi}, \\
W_{\overline{\psi}} W_{\psi f} W_{\psi f} & d_{\psi}.
\end{align*}
$$

where

$$
\begin{align*}
W_{\phi t}^{0} &= 1 & W_{\phi t}^{0} W_{\phi f}^{0} & W_{\phi f}^{0}, \\
W_{\phi f}^{0} &= 1 & W_{\phi f}^{0} W_{\phi f}^{0} & W_{\phi f}^{0}, \\
W_{\overline{\psi}}^{0} &= 1 & W_{\overline{\psi}}^{0} W_{\overline{\psi}}^{0} & W_{\overline{\psi}}^{0}, \\
W_{\psi f}^{0} &= 1 & W_{\psi f}^{0} W_{\psi f}^{0} & W_{\psi f}^{0}, \\
W_{\psi f}^{0} &= 1 & W_{\psi f}^{0} W_{\psi f}^{0} & W_{\psi f}^{0}.
\end{align*}
$$
Recalling that
\[ y = \begin{bmatrix} q \v E \v \dot{q} \v \dot{E} \end{bmatrix}, \quad u = \begin{bmatrix} u_1 \v u_2 \end{bmatrix}, \quad d = \begin{bmatrix} \varphi \v \psi \end{bmatrix}, \]

the transfer matrices from \( u \) and \( d \) respectively to \( y \) are given by
\[
W_0 \frac{W_{qe}}{W_{qE}} \frac{W_{qe}}{W_{qE}} \frac{W_{Ee}}{W_{EE}} \frac{W_{Ee}}{W_{EE}} \frac{W_{EE}}{W_{EE}} = \begin{bmatrix} W_{qE} & W_{qE} & W_{Ee} & W_{Ee} & W_{EE} \end{bmatrix}.
\]
