Catalytic Mechanism of the Oxidative Demethylation of 4-(Methoxymethyl)phenol by Vanillyl-Alcohol Oxidase

EVIDENCE FOR FORMATION OF A p-QUINONE METHIDE INTERMEDIATE*

(Received for publication, March 17, 1997, and in revised form, May 2, 1997)

The catalytic mechanism for the oxidative demethylation of 4-(methoxymethyl)phenol by the covalent flavoprotein vanillyl-alcohol oxidase was studied. Using H$_2^{18}$O, it was found that the carbonyl oxygen atom from the product 4-hydroxybenzaldehyde originates from a water molecule. Oxidation of vanillyl alcohol did not result in any incorporation of $^{18}$O.

Enzyme-monitored turnover experiments revealed that for both substrates a process involving flavin reduction is rate determining. During anaerobic reduction of vanillyl-alcohol oxidase by 4-(methoxymethyl)phenol, a relatively stable spectral intermediate is formed. Deconvolution of its spectral characteristics showed a typical pH-independent absorption maximum at 364 nm ($e$=$584$ nm$^{-1}$ cm$^{-1}$). A similar transient species was observed upon anaerobic reduction by vanillyl alcohol.

The rate of flavin reduction and synchronous intermediate formation by 4-(methoxymethyl)phenol is $3.3$ s$^{-1}$ and is fast enough to account for turnover ($3.1$ s$^{-1}$). The anaerobic decay of the intermediate was too slow ($0.01$ s$^{-1}$) to be of catalytical relevance. The reduced binary complex is rapidly reoxidized ($1.5 \times 10^5$ s$^{-1}$) and is accompanied with formation and release of product. Oxidation of free-reduced enzyme is an even faster process ($3.1 \times 10^9$ s$^{-1}$).

The kinetic data for the oxidative demethylation of 4-(methoxymethyl)phenol are in accordance with a ternary complex mechanism in which the reduction rate is rate-limiting. It is proposed that, upon reduction, a binary complex is produced composed of the p-quinone methide of 4-(methoxymethyl)phenol and reduced enzyme.

Vanillyl-alcohol oxidase (VAO, EC 1.1.3.13) from Penicillium simplicissimum is a novel flavoprotein that acts on a wide range of 4-hydroxybenzyl compounds (1, 2). VAO is a homooctamer, with each subunit containing 8$\alpha$-(N$^3$-histidyl)-FAD as a prosthetic group (3). During catalysis, the flavin cofactor is first reduced and subsequently reoxidized by molecular oxygen to yield hydrogen peroxide. In addition to the oxidation of aromatic alcohols also, demethylation, deamination, and hydroxylation reactions are being catalyzed as shown in Equation 1.

By its versatile catalytic potential, VAO may develop as a useful biocatalyst for applications in the fine chemical industry (4).

VAO is readily induced in P. simplicissimum by growth on veratryl alcohol (3). Although the enzyme is produced in relatively high amounts, the physiological role of the enzyme remained obscure for some time as VAO is not involved in the degradation of this aromatic alcohol. Only recently, it was found that the VAO-mediated oxidative demethylation of 4-(methoxymethyl)phenol is of metabolic relevance (5). When P. simplicissimum is grown on this phenolic methylether, VAO is induced and catalyzes the first step of the degradation pathway of 4-(methoxymethyl)phenol. Furthermore, analogs of 4-(methoxymethyl)phenol can easily be envisaged as physiological substrates enabling this ascomycetous fungus to cope with a wide variety of lignin decomposition products (5).

Previous studies have revealed some interesting mechanistic properties of VAO. A striking feature of all substrates is the necessity of a p-hydroxyl group that is probably a prerequisite for binding. Moreover, a large pK$_a$ shift observed upon binding of the competitive inhibitor isoegenol indicates that substrates become deprotonated upon binding (1). For the reaction of VAO with the substrate eugenol, it was established that the oxygen atom incorporated into the formed product coniferyl alcohol is derived from water. From these results, a catalytic mechanism for the hydroxylation of eugenol was proposed which involves formation of a p-quinone methide intermediate (1). A similar catalytic mechanism has been proposed for the hydroxylation of 4-alkylphenols by the flavocytochrome, p-cresol methylhydroxylase (6). So far, no real evidence has ever been presented for the formation of p-quinone methide intermediates during flavin-mediated reactions. We have suggested that hydride transfer to the oxidized flavin cofactor following deprotonation of the substrate would be a feasible sequence of reactions leading to the formation of the labile p-quinone methide intermediate (1). Hydride transfer mechanisms have been proposed for several other flavin-dependent oxidases like meth-
Enzymes and Reagents—VAO was purified from *P. simplicissimum* as described by De Jong et al. (3) with the modification that a 200-liter fermentor was used for cultivation and that cells were disrupted using a Manton-Gaulin homogenizer. The ratio $A_{280}/A_{439}$ for the purified enzyme was 11.0. Glucose oxidase (grade II) and catalase were from Boehringer Mannheim. $H_2^{18}O$ (97 mol/100 mol $^{16}O$) was obtained from Campro (Veenendaal, The Netherlands). Vanillyl alcohol, vanillin (4-hydroxy-3-methoxybenzaldehyde), 4-hydroxybenzaldehyde, and 4-(methoxymethyl)phenol were purchased from Aldrich.

Analytical Methods—All experiments were performed at 25 °C in 50 mM phosphate buffer, pH 7.5, unless stated otherwise. VAO concentrations were calculated from the molar absorption coefficient of the oxidized form ($\varepsilon_{439\text{ nm}} = 12.5 \text{ mM}^{-1} \text{ cm}^{-1}$ (3)).

Isotope Labeling Experiments—For $^{18}O$ incorporation experiments, 195 $\mu$L of $H_2^{18}O$ was added to 400 $\mu$L of 1.0 mM substrate solutions. After addition of VAO (25 $\mu$L, 200 $\mu$M) and catalase (5 $\mu$L, 100 $\mu$M), the samples were incubated for 5 min at 25 °C and subsequently twice extracted with 500 $\mu$L diethyl ether. After evaporation, the samples were analyzed by GC/MS. GC/MS analysis was performed on a Hewlett Packard HP 5973 MSD and HP 6890 GC equipped with an HP-5 column.

**Steady-state Kinetics**—Steady-state kinetic experiments were performed essentially as described earlier (1). Vanillyl alcohol and 4-(methoxymethyl)phenol activity were determined spectrophotometrically by recording the formation of vanillin ($\varepsilon_{340\text{ nm}} (pH 7.5) = 14.0 \text{ mM}^{-1} \text{ cm}^{-1}$) and 4-hydroxybenzaldehyde ($\varepsilon_{340\text{ nm}} (pH 7.5) = 10.0 \text{ mM}^{-1} \text{ cm}^{-1}$), respectively. Oxygen concentrations were varied by mixing buffers saturated with 100% nitrogen and 100% oxygen in different ratios.

Stopped-flow Kinetics—Stopped-flow kinetics were carried out with a Hi-Tech SF-51 apparatus equipped with a Hi-Tech M300 monochromator diode-array detector (Salisbury, United Kingdom). Spectral scans were collected each 10 ms. For accurate estimation of rate constants, single wavelength kinetic traces were recorded at 439 nm using a Hi-Tech SU-40 spectrophotometer. In anaerobic experiments, solutions were flushed with argon and contained glucose (10 mM) and glucose oxidase (0.1 $\mu$M) to ensure anaerobic conditions. To determine the maximal rate of enzyme reduction by 4-(methoxymethyl)phenol and vanillyl alcohol, apparent rates were determined at five different substrate concentrations. To obtain accurate estimations of reduction rate constants observed during anaerobic reduction by vanillyl-alcohol, measurements were also performed at 355 and 393 nm. Deconvolution analysis of spectral data was performed using the Specfit Global Analysis program Version 2.10 (Spectrum Software Assn., Chapel Hill, NC). Solutions containing reduced enzyme (5 $\mu$M) were prepared by titrating argon flushed enzyme solutions with dithionite. For generation of the reduced enzyme intermediate complex, the enzyme was anaerobically mixed with a 1.5-fold excess of 4-(methoxymethyl)phenol. Reoxidation of reduced enzyme was measured by monitoring the increase in absorbance at 439 nm after mixing with molecular oxygen. Reduced enzyme (5.0 $\mu$M) was mixed with varying concentrations of molecular oxygen (10, 21, 50, and 100% saturation) to determine the second-order rate constants for the reoxidation of protein-bound flavin.

For enzyme-monitored turnover experiments (11), air-saturated enzyme and substrate solutions were mixed in the stopped-flow instrument after which the redox state of the flavin cofactor was recorded at 439 nm.
relatively small (12, 13). Fig. 2 shows a secondary plot of the extrapolated turnover rates at saturating oxygen concentrations versus the concentration of 4-(methoxymethyl)phenol. From this, the steady-state kinetic parameters with 4-(methoxymethyl)phenol could be calculated (Table I). The steady-state kinetic parameters for vanillyl alcohol were similarly determined (again showing series of parallel secondary plots) and were in the same range as for 4-(methoxymethyl)phenol ($k_{cat} = 3.3 \times 10^3 \, \text{M}^{-1} \cdot \text{s}^{-1}$, $K_m(S) = 55 \, \text{mM}$, $K_m(O_2) = 24 \, \mu M$). The relatively high $K_m$ value for vanillyl alcohol might result from the more polar character of the benzylic moiety compared with 4-(methoxymethyl)phenol (1).

By measuring the redox state of the flavin cofactor during catalysis (enzyme-monitored turnover), information can be obtained about the rate-limiting step (11). For this, the enzyme was aerobically mixed in the stopped-flow apparatus with a high concentration of substrate. It should be noted here that due to the low solubility of vanillyl alcohol and 4-(methoxymethyl)phenol, the substrate concentrations (500 $\mu M$) were not fully saturating. During turnover, the absorbance at 439 nm was monitored to detect the amount of oxidized enzyme present. Fig. 3 shows that with both substrates most of the enzyme is in the oxidized state during turnover. The fraction of oxidized enzyme for both substrates was almost identical, 0.86 for 4-(methoxymethyl)phenol and 0.91 for vanillyl alcohol (Fig. 3). This suggests that processes involving flavin reduction are slower than those of the oxidative part of the catalytic cycle.

**Reducive Half-reaction**—To study the reductive half-reaction of VAO, the oxidized enzyme was mixed with substrate in the stopped-flow spectrophotometer under anaerobic conditions. Reduction of VAO by 4-(methoxymethyl)phenol was a monophasic process when monitored at 439 nm. Diode-array detection revealed that anaerobic enzymatic reaction with 4-(methoxymethyl)phenol resulted in the formation of a species with an intense absorption maximum at 364 nm ($\epsilon_{364 \text{ nm}} = 46 \, \text{mM}^{-1} \cdot \text{cm}^{-1}$) (Fig. 4). During this process, the flavin becomes fully reduced as evidenced by the decrease in absorbance at 439 nm. This indicates that the rate of the reverse reaction must be relatively small. The rate of flavin reduction at saturated substrate concentrations was in the same range as the turnover rate (Table I). pH-dependent anaerobic reductions by 4-(methoxymethyl)phenol revealed that the spectral properties of the formed intermediate were not influenced between pH 6.8 and 7.9. Furthermore, reduction at the tested pH values did not result in a significant change of the rate of reduction. When the spectral changes were followed on a longer time scale (>20 s), a very slow decay of the high absorbance intermediate was observed. The resulting spectrum could be characterized as the composite of reduced enzyme and the product 4-hydroxybenzaldehyde. Indicative for aldehyde formation was the increase in the absorbance at 364 nm (Fig. 4).
under anaerobic conditions was estimated to be 0.01 s

Typical absorption maximum at 362 nm (Fig. 5, inset) significantly be influenced by bound ligands (L).

For flavoprotein oxidases, the rate of enzyme reoxidation can significantly be influenced by bound ligands (L in Equation 3) (15). For instance, in the case of D-amino acid oxidase from yeast, it was reported that reoxidation of free-reduced enzyme is not of catalytical significance as it is significantly slower

\[ E_{\text{red}}(\sim L) + O_2 \rightarrow E_{\text{ox}}(\sim L) + H_2O_2 \]  

(Eq. 3)
than the turnover rate. Only the rate for reoxidation of the reduced enzyme product complex was high enough to account for the observed turnover rate, which is in agreement with the proposed ternary complex mechanism (16). When the reoxidation rate of reduced VAO was studied in the presence of vanillyl alcohol or its product vanillin, the rates of flavin reoxidation were significantly lower as compared with free-reduced enzyme (1.4 × 10^5 and 1.1 × 10^2 M⁻¹ s⁻¹, respectively).

As reduction by 4-(methoxymethyl)phenol resulted in a relatively stable reduced enzyme-intermediate complex \((E_{\text{red}} \sim Q)\), the rate of reoxidation of this complex was measured as well. Therefore, after reducing VAO by 4-(methoxymethyl)phenol, the reduced complex was mixed in the stopped-flow apparatus with oxygen to measure the rate of formation of oxidized enzyme. It was found that the complex readily reacted with oxygen in a fast monophase process reoxidizing the flavin with simultaneous product formation as evidenced by the increase in absorbance at 335 nm. By varying the oxygen concentration, the second order rate constant for reoxidation of the reduced enzyme intermediate complex was estimated to be 1.5 × 10^5 M⁻¹ s⁻¹. Similar values for the rate of reoxidation have been reported for other flavin-dependent oxidases (15-18). The apparent turnover rate with 4-(methoxymethyl)phenol during steady-state conditions is much slower as the rate of reoxidation. Evidently, reoxidation is not determining the rate of catalysis in case of 4-(methoxymethyl)phenol, which is in agreement with the enzyme monitored turnover results.

**DISCUSSION**

The experiments described here represent the first study on the kinetic mechanism of VAO catalyzed reactions. Furthermore, evidence is presented for the participation of p-quinone methides in the catalytic mechanism of VAO. Previously, we proposed a reaction mechanism for the conversion of eugenol by VAO, which included formation of a p-quinone methide intermediate (1). Addition of water to this putative electrophilic intermediate would result in the formation of the product coniferyl alcohol. From isotopic labeling experiments, we have demonstrated in the present study the involvement of water during the VAO catalyzed demethylation of 4-(methoxymethyl)phenol. VAO-mediated demethylation of this physiological substrate resulted in the introduction of an oxygen atom originating from a water molecule. This indicates that during catalysis the substrate is activated, after which water can attack the Cα-atom. In contrast, with vanillyl alcohol, no oxygen atom derived from water is introduced into the aromatic product vanillin.

The rapid reaction data presented in this paper showed the formation of intermediate reduced enzyme complexes during the reductive half-reaction. Anaerobic reduction of VAO by 4-(methoxymethyl)phenol revealed the formation of an eminently stable intermediate with typical spectral properties \((\epsilon_{364 \text{ nm}} = 46 \text{ mm}^{-1} \text{ cm}^{-1})\). The spectral characteristics of the intermediate binary complex did not resemble any known flavoprotein oxidase complex. Intermediate complexes formed during catalysis of, for example, lactate monooxygenase (19) and d-amino acid oxidase (20) have specific absorbances above 500 nm and are due to a charge transfer interaction between the reduced enzyme and product. The formation of a flavin adduct as intermediate in the reaction of VAO with 4-(methoxymethyl)phenol is rather unlikely as the spectral properties of the intermediate complex do not resemble any known flavin adduct spectrum (21). However, the spectral properties of the formed intermediate generated during the anaerobic reaction of VAO with 4-(methoxymethyl)phenol closely resembled reported spectra of several p-quinone methides of structural analogs of the phenolic substrate \((\lambda_{\text{max}} \sim 360 \text{ nm}, \epsilon \sim 40 \text{ mm}^{-1})\) as obtained by chemical synthesis or flash photolysis of the corresponding phenols (22-26). However, spectra of the p-quinone methides of vanillyl alcohol and 4-(methoxymethyl)phenol have never been described. These compounds are highly unstable because of the lack of an electron donating group to stabilize the electrophilic methide carbon atom. The data presented here for VAO-mediated conversion of 4-(methoxymethyl)phenol are all consistent with formation of a p-quinone methide intermediate, which subsequently will react with water.

The p-quinone methide formed from this substrate is highly stabilized in the active site as long as the enzyme remains reduced. This suggests that the active site of the reduced enzyme intermediate complex is solvent inaccessible. Upon reoxidation of the flavin, the p-quinone methide intermediate rapidly reacts with water, indicating that during this process local structural changes occur leading to a more solvent accessible active site. The p-quinone methide is hydrated to form the unstable hemiacetal product of 4-(methoxymethyl)phenol, which decomposes rapidly to give 4-hydroxybenzaldehyde (Equation 4). The presence of reduced glutathione during turnover of 4-(methoxymethyl)phenol did not influence the stoichiometric formation of the aldehyde product, indicating that hydration of the formed p-quinone methide occurs in the enzyme active site.

With vanillyl alcohol also, a transient intermediate spectrum was observed during anaerobic reduction with similar spectral characteristics as with 4-(methoxymethyl)phenol. However, with vanillyl alcohol, only half of the flavin is reduced when the maximal amount of the high absorbance intermediate is formed, indicating that the intermediate is already decomposed when the enzyme is fully reduced. When the decay of the intermediate during the second reductive phase is acknowledged, the molar absorption coefficient of the intermediate may well resemble that of the 4-(methoxymethyl)phenol p-quinone methide intermediate. The instability of the formed vanillyl alcohol p-quinone methide may well explain why during oxidation of this alcohol water is not involved in the formation of the aldehyde product. Decay of the initial intermediate formed may correspond to the autocatalytic decomposition of the vanillyl alcohol p-quinone methide leading to vanillin. The biphasic reduction can be interpreted to result from two reactive conformations of the enzyme of which one is able to reduce the flavin rapidly while the other conformation is slow in reduction. In view of this, it is worthy to note that VAO is an octamer composed of relatively stable dimers (27). Another explanation for the partial reduction observed with vanillyl alcohol is a reversible reduction of the flavin by vanillyl alcohol, which results in an equilibrium of oxidized and reduced enzyme in anaerobic reduction experiments. When \(k_{2} \sim k_{-2}\), the ratio of oxidized and reduced enzyme will be 0.5, leading to an apparent partial reduction as shown in Fig. 5. The second phase observed during the reductive half-reaction might then represent product release, which would also result in total reduction of the flavin. In that case, the turnover rate for vanillyl alcohol oxidation would be determined by product release, which has also been found for several other flavoprotein oxidases (11, 13).
Catalytic Mechanism of Vanillyl-Alcohol Oxidase

Scheme 1. Proposed kinetic mechanism for the oxidative demethylation of 4-(methoxymethyl)phenol by vanillyl-alcohol oxidase. E-Fl$_{ox}$ = oxidized VAO; E-Fl$_{red}$ = reduced VAO; $S$ = 4-(methoxymethyl)phenol; $Q$ = $p$-quinone methide of $S$; $P$ = 4-hydroxybenzaldehyde.

However, analysis of the substrate-dependent reduction rates revealed that the reversible step of reduction must be very small ($k_2 < 0.5$ s$^{-1}$) and is too small to explain the relatively high amount of oxidized enzyme present after the first phase of flavin reduction. Furthermore, enzyme-monitored turnover experiments showed that the enzyme is mainly in the oxidized state (91%) during steady-state turnover. As a consequence, with vanillyl alcohol, a reductive step is limiting the turnover rate also.

From the rapid reaction kinetic parameters obtained in this study, it can be concluded that VAO catalyzes the oxidative demethylation of 4-(methoxymethyl)phenol via a ternary complex mechanism. Also, the parallel lines pattern of Lineweaver-Burk plots found for the steady-state kinetics are in accordance with a ternary complex mechanism as $k_2$ is negligibly small and $k_3$ is relatively large (Table I). Because $k_3$ is very small, only a small portion of enzyme will react via a ping-pong mechanism as represented by the left cycle in Scheme I. From single turnover experiments, it could be deduced that the rate of flavin reduction, i.e., formation of the binary complex ($k_2 = 3.3$ s$^{-1}$), is by far the rate determining step in catalysis ($k_{cat}$ = 3.1 s$^{-1}$). The enzyme-monitored turnover results are also consistent with the proposed kinetic mechanism. When the formation of the Michaelis-Menten complex is a relatively fast process (at infinite substrate concentrations), the ratio of enzyme in the oxidized state during steady-state can be calculated by the following.

$$\frac{E_{cat}}{E_{mon}} = \frac{1/(k_2) + 1/(k_3)}{(1/(k_2) + 1/(k_3) + 1/(k_4))}$$

(Eq. 5)

For 4-(methoxymethyl)phenol, the calculated ratio is 0.92 ($k_3 = 3.0$ s$^{-1}$ at 500 $\mu$M), which compares quite well with the experimental obtained value of 0.86. This indicates that the mechanism-based calculated rate of product release ($k_4 = 50$ s$^{-1}$) is a reasonable approximation.

Taken together, the kinetic data are consistent with a ternary complex mechanism including (right cycle of Scheme I) 1) formation of a Michaelis-Menten complex, 2) flavin reduction and synchronous formation of the reduced enzyme intermediate complex, 3) reoxidation of the reduced enzyme complex by molecular oxygen with the concomitant conversion of the inter-
