PET Center, Department of Neurology and Department of Pulmonary Diseases, University Hospital and Department of Analytical Chemistry and Toxicology, University Center for Pharmacy, Groningen, The Netherlands; Institute of Pharmacology and Toxicology, Martin Luther University, Halle/Saale, Germany

We evaluated the suitability of fluorocarazolol for in vivo studies of cerebral beta-adrenoceptors because (S)-1'-'[18F]fluorocarazolol has a higher affinity to beta-adrenoceptors than to serotonergic receptors (pK<sub>A</sub> of 8.1) and rapidly crosses the blood-brain barrier. Methods: The (S)-1'-'[18F]fluorocarazolol (74 MBq, >37 TBq/mmol) was intravenously administered to healthy volunteers on two separate occasions with an interval of at least 1 wk. The initial injection was without pretreatment, but before the second injection, the volunteers received the beta blocker (+)-pindolol (3 × 5 mg orally, during 18 hr). The brain was studied with a PET camera in dynamic mode. Results: Uptake of radioactivity occurred because downregulation of beta-adrenoceptors and serotonin receptors takes place only after chronic drug administration (13,14). Receptor downregulation could be a prerequisite of the antidepressant activity (15). Receptor density may also change when noradrenergic innervation is impaired. Deterioration of noradrenergic neurons occurs such as in the Parkinson dementia complex (16). Most of these observations have been made in autopsy studies, in binding assays to human lymphocytes and cultured cells or in animal experiments. None of these relationships has been observed in intact humans by external detection with receptor-specific radioligands. Fluorocarazolol, a fluorinated analog of the potent beta-blocker carazolol has been useful in vivo studies of beta-adrenoceptors, both in experimental animals (17–19) and in humans (20). Uptake in the rat brain is saturable, sensitive to selective beta-adrenoceptor antagonists and stereospecific. We now report the first results obtained with (S)-1'-'[18F]fluorocarazolol-PET to visualize the distribution of beta-adrenoceptors in the brain of healthy volunteers.
**MATERIALS AND METHODS**

**Radioligand**

(S)-Desisopropylcarazolol (enantiomeric excess >98%) was prepared as reported previously (17). (S)-1'-[18F]fluorocarazolol was synthesized by reacting the precursor with [18F]fluoroacetone (17,19) and purified by HPLC. The specific activity was >99.8%. The ligand was dissolved in 0.5 ml ethanol/pro-pylene glycol/0.9% NaCl (1/2/2 v/v/v). Before injection, this solution was filtered (0.22 μm) and purified by HPLC. The specific activity was 75 ± 35 MBq/mmol and a body weight of 70 kg. The resulting IC50 values were converted to Kd values according to the Cheng and Prusoff equation (22): 

**In Vitro Binding Assays**

The affinity of (S)-1'-fluorocarazolol to β1- and β2-adrenoceptors was assessed in membranes prepared from human right atrial tissue and human lymphocytes, respectively, using (-) [18F]fluorocarazolol as the radioligand (21). Affinity of (S)-1'-fluorocarazolol to 5HT1A receptors was determined in bovine hippocampal membranes using 1.0 nM [3H]-8-OH-DPAT as the radioligand; the affinity to 5HT1B receptors was measured in rat striatal membranes, using 150 pM [125I]iodocyanopindolol in the presence of 60 μM (-)-isoproteranol. The resulting IC50 values were converted to Kd values according to the Cheng and Prusoff equation (22): $K_d = IC_{50}/([S]/K_a + 1)$, where IC50 = concentration of florocarazolol that inhibited radioligand binding by 50%, [S] = concentration of radioligand in the assay and $K_a$ = equilibrium dissociation constant of the radioligand. The β1- and β2-adrenoceptor assays were performed by the Institut für Pharmakologie und Toxikologie, Halle, Germany; affinities to 5HT1A and 5HT1B receptors were determined by NovaScreen (Hanover, MD).

**Human Volunteers**

Healthy volunteers were recruited through advertisements in a local newspaper. Excluded were people with: (a) a positive history regarding neuropsychiatric disease; (b) use of antidepressants, beta-blockers, beta-mimetics or theophylline; (c) high blood pressure or heart failure; or (d) pregnancy or suspected pregnancy. All volunteers were informed about the purpose and hazards of the experiment both orally and in writing and gave informed consent.

**Study Protocol**

At the beginning of the study, a cannula was placed in a vein of one of the lower forearms. Another cannula was placed in a radial artery of the contralateral arm after patency of the ulnar artery had been proven by the Allen test. The arterial cannula was inserted under local anesthesia with lidocain. The venous cannula was used for injection of the ligand, the arterial line for blood sampling.

The volunteer was then placed on the PET camera (Siemens ECAT 951/31, Knoxville, TN, FWHM = 6 mm, axial field of view 10.8 cm, images reconstructed in 31 planes). Volunteers were positioned to the orbito-meatal line. Next, a transmission scan was produced using the internal 68Ge/68Ga sources to correct for attenuation. Cerebral blood flow was assessed by bolus injection of 1.85 GBq (50 mCi) H215O (using a Medrad OP-100 remote-controlled pump, total volume 40 ml at a speed of 8 ml/sec−1) to make sure that no perfusion defects were present. Data acquisition was started at the onset of injection: four frames of 5 sec were followed by one frame of 10 sec, two frames of 30 sec and one frame of 2 min. Total duration of the study was 3.5 min. After an interval of at least 10 min (i.e., 5 half-lives of 15O), (S)-1'-[18F]fluorocarazolol (on average 63 MBq = 1.7 mCi) was injected over a period of 1 min, using the Medrad pump.

Data acquisition was started at the onset of injection: eight frames of 15 sec were followed by four frames of 30 sec, four frames of 1 min, four frames of 2 min, six frames of 4 min and two frames of 10 min. Total duration of the study was 60 min. Arterial blood samples (2 ml) were drawn at 0.5-min intervals during the initial 5 min and at 10-min intervals from 10 to 60 min postinjection. Radioactivity in plasma and in a cell pellet (5 min 3000 g) was determined in all samples using a gamma counter that was cross-calibrated with the PET camera. Additional samples (3 ml) drawn at 1, 2, 5, 10, 20, 40 and 60 min were used for metabolite analysis. Plasma was analyzed for the presence of (S)-1'-[18F]fluorocarazolol and radioactive metabolites by direct injection onto an internal-surface reversed-phase column 150 × 4.6 mm; mobile phase 10 mM K2HPO4:acetonitrile 90:10; pH 7.5; flow rate 1.5 ml.min−1 as published previously (23).

After an interval of at least 1 wk, the volunteer returned for the second part of the study in which the influence of a beta-adrenoceptor antagonist on tissue uptake of (S)-1'-[18F]fluorocarazolol was assessed. Each volunteer took pindolol orally: 5 mg on the evening before the experiment, 5 mg on the morning before the experiment and 5 mg 60 min before injection of the radioligand.

Cannulas were placed in a vein of each of the lower forearms. No arterial catheter was used in the second part of the study to keep inconvenience to the volunteer to a minimum. One cannula was used for injection and the other for blood sampling. Tracer injection, data acquisition and sampling were performed as on day one.

**Data Analysis**

ROIs were drawn by hand on white matter (corpus callosum), posterior part of the gyrus cinguli including precuneus, striatum, thalamus and cerebral cortex (comprising both hemispheres in a section just superior to the border of white and gray matter). Time-activity curves for the ROIs were calculated using ECAT software (version 6.5D) running on a Sun/ Sparc (Mountain View, CA) workstation. All data were normalized to an injected radioactivity of 74 MBq (2 mCi) and a body weight of 70 kg. The time-activity data were exported to an IBM-compatible PC and characterized using a nonlinear regression data analysis program (EnzFitter, Elsevier Biosoft, Cambridge, U.K.). Differences between groups were tested using one-way analysis of variance and appropriate software (Statistix, NH Analytical, Roseville, MN). A two-tailed probability smaller than 0.05 was considered statistically significant.

**RESULTS**

**General**

Preliminary in vitro assays showed that (S)-1'-fluorocarazolol binds preferentially to beta-adrenoceptors (pKd at the β1-subtype: 9.4, at the β2-subtype: 10.0) and has less affinity to 5HT1A (pKd 7.4) and 5HT1B (pKd 8.1) serotonergic sites. These results encouraged us to initiate the pilot study in healthy volunteers.

Details regarding the participants and the study protocol are presented in Table 1. None of the volunteers showed any symptoms of heart failure, hypertension or neuropsychiatric disease.

**Distribution of Radioactivity within the Brain**

The cerebral distribution of the flow tracer, H215O, delineated gray matter as expected. Representative images acquired after injection of S-1'-[18F]fluorocarazolol are presented in Figure 1. Transaxial cross-sections in the time frame 14–60 min are...
displayed. In the initial study (without pindolol), gray matter was clearly demarcated from white matter. Uptake of radioactivity was especially high in the cortical areas (posterior cingulate, precuneus) and the corpus striatum (caudate and putamen, Fig. 1). Low uptake occurred in the thalamus. The lowest uptake was observed in the white matter (corpus callosum, see Fig. 1). This relatively high striatal uptake and low uptake in the thalamus contrasted with the more even distribution of radioactivity seen in the $H_2\text{O}$ scans. In one volunteer, a hot spot was visible just ventrally to the cerebellum and interpreted as the putative locus coeruleus (see Fig. 1). After ingestion of pindolol, cerebral uptake of radioactivity was strongly (>two-fold) suppressed and gray matter was no longer demarcated, as the distribution of radioactivity became virtually homogeneous throughout the brain (see Fig. 1 and Table 2). The hot spot near the cerebellum also disappeared after preloading of the volunteer with pindolol.

### Kinetics of Cerebral (-)-$F$-Fluorocarazolol Uptake

After injection of the radioligand, cortical levels of radioactivity rapidly rose to a maximum followed by an equally rapid, small decline to a relatively stable plateau that was reached within 3 min (Fig. 2). Pindolol accelerated the washout of radioactivity from the cortex (Fig. 2) and it reduced cortical radioactivity to <50% of the control at 60 min postinjection. In contrast to the data for cerebral cortex, uptake of radioactivity in the white matter of the corpus callosum was not significantly affected by pindolol (Fig. 2). Uptake in the corpus callosum was about equal to that in the cortex of pindolol-treated subjects at >30 min postinjection (Fig. 2).

If uptake of radioactivity in the presence of pindolol is considered to represent nonspecific binding, ratios of total-to-nonspecific binding can be calculated. In the cerebral cortex, this parameter increased during the whole period of PET scanning, and it was not yet maximal after 60 min (Fig. 3). The curve fitted to the data suggests that a maximum of 2.52 is reached with a first-order rate constant of 0.0222 min$^{-1}$ (i.e., time required to reach 50% of the maximum = 31 min).

Washout of radioactivity from the brain of untreated subjects is slow and it appears to be different in different brain areas (faster in thalamus than in other areas of the brain). The relative amount of radioactivity which remains in different areas at 60

*Significant differences between the untreated and pindolol-preloaded condition (one-way ANOVA P < 0.05).

Tissue uptake of radioactivity is expressed as camera units (ECAT cts/pixel/sec) × 10⁴. Data are an average ± s.e.m. of all dynamic studies (five in the control condition, four after pindolol preload); values were normalized to an injected dose of 74 MBq (2 mCi).

min is: cingulate cortex plus precuneus = striatum > other parts of the cortex > thalamus > white matter of the corpus callosum.

Effect of Beta-Blockade on Radioligand Clearance and Metabolism

Preloading of volunteers with pindolol affects clearance and metabolism of the radioligand (Fig. 4). Levels of radioactivity in the circulation at 20–60 min postinjection are higher, and the fraction of plasma radioactivity representing parent compound also is higher after treatment of volunteers with pindolol. Similar results had been obtained in a previous study of beta-adrenoceptors in the human thorax (20).

DISCUSSION

Selectivity of Fluorocarazolol

Many beta-blockers interact with central serotonergic sites (24–26). Iodocyanopindolol (24,26), pindolol (27), carteolol (25) and propranolol (25,27) bind almost equally well to 5HT₁A and/or 5HT₁B receptors as to beta-adrenoceptors. In contrast, hydrophilic atenolol (25) and CGP-12177 (26) are selective beta-adrenoceptor antagonists. Unfortunately, ¹¹C-atenolol and ¹³C-CGP 12177 cannot be used for PET studies of the brain as CGP 12177 hardly crosses the blood-brain barrier (28,29), while the affinity of atenolol is too low for successful beta-adrenoceptor imaging (30). Because of its lipophilicity [log P 2.2 at pH 7.4, (19)], fluorocarazolol was expected to show rapid transport over the blood-brain barrier. Indeed, we have observed that (S)-l'⁻¹⁸F]fluorocarazolol enters rat brain and it demonstrates significant specific binding in cerebral cortex and cerebellum (18). In vitro binding assays have shown a much higher affinity of fluorocarazolol to beta-adrenoceptors than to 5HT₁A or 5HT₁B receptors (see Results). The 20- to 400-fold selectivity of fluorocarazolol for beta-adrenoceptors indicates that serotonergic sites will not significantly contribute to the specific binding in the brain after administration of a nanomolar dose of the radioligand (see also below).

Distribution of Binding Sites for Fluorocarazolol within the Brain

Whether a ligand binds to receptors in the living human brain can be determined by assessing whether the regional distribution of radioactivity after drug injection parallels the distribution of receptors known from post mortem autoradiography, and by examining whether administration of an excess of an...
unlabeled receptor antagonist blocks this specific regional distribution. Both approaches were used in this study.

After administration of (S)-1'-[18F]fluorocarazolol to volunteers, distribution of radioactivity within the brain was homogeneous. Relatively high uptake was observed in the striatum and cortical areas (especially cingulate cortex and precuneus). Low levels of radioactivity were present in the thalamus and the lowest in white matter. Such a distribution corresponds to the localization of beta-adrenoceptors known from post mortem autoradiography with the ligands [125I]iodocyanopindolol, [125I]iodopindolol and [3H]CGP 12177: high beta-adrenoceptor densities are found in caudate and putamen (2,13,31–33), moderate to high densities in various cortical areas (2,13,31–33) and low densities in thalamus (2,13,32) and white matter (33,34).

With the most selective beta-adrenoceptor ligand, [125I]iodocyanopindolol, and cortical areas (especially cingulate cortex and precuneus). Local differences in tissue uptake of radioactivity within the brain observed 14–60 min after injection of the radioligand were absent when the volunteers had ingested pindolol (Fig. 1). Uptake in all regions then became similar to that in the corpus callosum. Thus, administration of an excess of an unlabeled receptor antagonist blocked the specific regional distribution of (S)-1'-[18F]fluorocarazolol within the brain.

CONCLUSION

(S)-1'-[18F]fluorocarazolol, a potent beta-adrenergic receptor antagonist, specifically accumulated in gray matter after in vivo administration to humans. Uptake is particularly high in the striatum and in various cortical areas, regions with a high density of beta-adrenoceptors. Preferential localization in striatum and cortex is blocked by administration of an excess of an unlabeled beta-adrenoceptor antagonist (pindolol). These data, combined with results from animal experiments, indicate that the distribution of radioactivity reflects radioligand binding to beta-adrenoceptors. White matter of the corpus callosum can probably be used as a reference region to estimate nonspecific binding. It may now be feasible to assess the role of human cerebral beta-adrenoceptors in the action of antidepressant drugs and in disorders such as depression and schizophrenia.

Cerebral Sparganosis: Increased Uptake of Technetium-99m-HMPAO

Dong-Ling You, Kai-Yuan Tzen, Pan-Fu Kao, Yat-Sen Ho and Chun-Che Chu

Departments of Nuclear Medicine, Pathology and Neurology, Chang Gung Memorial Hospital, Taipei, Taiwan

Cerebral sparganosis is an extremely rare intracranial parasitic infectious disease. We report findings of 99mTc-HMPAO cerebral perfusion SPECT in a case with cerebral sparganosis. SPECT revealed an irregularly shaped area with markedly increased 99mTc-HMPAO uptake in the parasitic infectious region of the cerebrum. Both white and gray matter was involved, the white matter involved predominantly. Decreased perfusion to the right cerebellum, suggesting cross cerebellar diaschisis, was also demonstrated. This article illustrates that cerebral sparganosis is one of the causes of increased 99mTc-HMPAO uptake in the cerebrum and should be considered clinically if present.

Key Words: sparganosis; technetium-99m-HMPAO; cerebral perfusion SPECT

J Nucl Med 1997; 38:939-941

This article demonstrates the findings of 99mTc-HMPAO cerebral perfusion SPECT in a case with cerebral sparganosis.

CASE REPORT

A 74-yr-old man patient presented to our hospital with seizure and progressive weakness of the right side of his body for 1 mo. The patient did not have a fever. Neurological examination revealed decreased sensation and muscle power of the right side of the body. The white blood cell count on admission was 5,900/mm³, and the differentiation showed 70% granulocytes, 19% lymphocytes, 4% eosinophils and 7% monocytes. EEG revealed continuous, focal, slow waves over the left frontotemporoparietal area. Brain CT revealed a cystic, enhancing mass lesion at left temporal area (Fig. 1). Brain MRI also revealed a mass lesion with hypointensity on T1-weighted images and hyperintensity on T2-weighted images (Fig. 1) with heterogeneous enhancement at the left temporal area. Based on the clinical presentations, examinations, CT and MRI findings brain tumor was suspected.

Technetium-99m-HMPAO cerebral perfusion SPECT was arranged to evaluate the regional blood flow to the intracranial mass lesion. SPECT imaging was performed using a triple-head gamma camera equipped with fan-beam collimators. Acquisition was started 20 min after an intravenous injection of 925 MBq (25 mCi) 99mTc-HMPAO in 120 projections, 3° apart, in a 128 × 128 matrix.
