PURPOSE Immunochemotherapy with rituximab plus cyclophosphamide, doxorubicin, vincristine, and prednisone (R-CHOP) has become standard of care for patients with diffuse large B-cell lymphoma (DLBCL). This randomized trial assessed whether rituximab intensification during the first 4 cycles of R-CHOP could improve the outcome of these patients compared with standard R-CHOP.

PATIENTS AND METHODS A total of 574 patients with DLBCL age 18 to 80 years were randomly assigned to induction therapy with 6 or 8 cycles of R-CHOP-14 with (RR-CHOP-14) or without (R-CHOP-14) intensification of rituximab in the first 4 cycles. The primary end point was complete remission (CR) on induction. Analyses were performed by intention to treat.

RESULTS CR was achieved in 254 (89%) of 286 patients in the R-CHOP-14 arm and 249 (86%) of 288 patients in the RR-CHOP-14 arm (hazard ratio [HR], 0.82; 95% CI, 0.50 to 1.36; P = .44). After a median follow-up of 92 months (range, 1-131 months), 3-year failure-free survival was 74% (95% CI, 68% to 78%) in the R-CHOP-14 arm versus 69% (95% CI, 63% to 74%) in the RR-CHOP-14 arm (HR, 1.26; 95% CI, 0.98 to 1.61; P = .07). Progression-free survival at 3 years was 74% (95% CI, 69% to 79%) in the R-CHOP-14 arm versus 71% (95% CI, 66% to 76%) in the RR-CHOP-14 arm (HR, 1.20; 95% CI, 0.94 to 1.55; P = .15). Overall survival at 3 years was 81% (95% CI, 76% to 85%) in the R-CHOP-14 arm versus 76% (95% CI, 70% to 80%) in the RR-CHOP-14 arm (HR, 1.27; 95% CI, 0.97 to 1.67; P = .09). Patients between ages 66 and 80 years experienced significantly more toxicity during the first 4 cycles in the RR-CHOP-14 arm, especially neutropenia and infections.

CONCLUSION Early rituximab intensification during R-CHOP-14 does not improve outcome in patients with untreated DLBCL.

J Clin Oncol 38:3377-3387. © 2020 by American Society of Clinical Oncology

INTRODUCTION The overall survival (OS) of patients with diffuse large B-cell lymphoma (DLBCL) has improved significantly since the addition of rituximab to standard 3-week cyclophosphamide, doxorubicin, vincristine, and prednisone (R-CHOP-21) or dose-dense 2-week CHOP (R-CHOP-14).12 No significant benefits have been shown for R-CHOP-14 versus R-CHOP-21, and these regimens are currently standard treatments worldwide.34 However, approximately 40% of patients experience primary refractory disease or relapse, which is often fatal.56 Therefore, further improvement of first-line therapy is needed.

The dose and schedule of rituximab in the R-CHOP combination are largely empirically determined on historical grounds. Few phase II studies have explored variations of the rituximab schedule in combination with CHOP in elderly patients with DLBCL.7 8 In a single
 study in which patients were treated with rituximab administered in shorter intervals at the beginning of treatment and over a prolonged period of time, a better outcome for patients with poor prognosis with International Prognostic Index (IPI) score of 3 to 5 compared with historical controls was reported. The same group reported significantly reduced rituximab clearance in elderly women compared with elderly men. During standard R-CHOP-14 treatment, serum levels of rituximab show a gradual increase up to cycle 5, reaching a plateau thereafter. The lag time of 5 cycles may result in suboptimal rituximab serum levels, especially early during treatment. Therefore, treatment outcome may be improved through intensification of rituximab during the first 4 cycles by providing a steeper increase to the optimal therapeutic serum level as well as reaching a higher serum concentration within the large therapeutic window of rituximab.

To assess the efficacy of early rituximab intensification during first-line treatment in patients with DLBCL, we performed a prospective randomized phase III study to compare standard R-CHOP-14 with R-CHOP-14 combined with 4 extra administrations of rituximab during the first 4 induction cycles. Patients in complete remission (CR) after induction treatment were randomly assigned a second time between observation and rituximab maintenance. Here, we present the final analysis of the induction random assignment, including long-term follow-up data with a data cutoff of October 16, 2019.

PATIENTS AND METHODS

Patient Population

The HOVON-84 (Haemato Oncology Foundation for Adults in the Netherlands) study was an investigator-initiated prospective randomized phase III study conducted among 68 participating centers in the Netherlands, Denmark, and Belgium. The study was approved by the institutional review boards at all centers. Eligibility included previously untreated, biopsy-confirmed, CD20+ DLBCL according to local pathology and Ann Arbor stage II to IV. Patients between age 18 and 65 years and with an age-adjusted IPI score of 1 to 3 and patients between age 66 and 80 years and an age-adjusted IPI score of 0 to 3 were eligible. Central pathology review was performed as part of quality control (HOVON Pathology Facility and Biobank). CNS involvement, testicular DLBCL, primary mediastinal B-cell lymphoma, transformed indolent lymphoma, any solid malignancy in the preceding 5 years, and illnesses precluding study treatment rendered patients ineligible.

Computed tomography (CT) scanning and bone marrow biopsies were minimum mandatory staging procedures. Baseline 18F-fluorodeoxyglucose positron emission tomography (PET) scans were recommended but not mandated.

Random Assignment

After providing written informed consent, patients were randomly allocated to receive either R-CHOP-14 (arm A) or R-CHOP-14 with intensification of rituximab in the first 4 cycles (RR-CHOP-14; arm B). Random assignment was stratified by center, age group (18-65 vs 66-80 years), and age-adjusted IPI score using a minimization procedure, ensuring balance within each stratum and overall balance.

Treatment and Response Assessment

The R-CHOP-14 regimen consisted of 14-day cycles of intravenous cyclophosphamide 750 mg/m², doxorubicin 50 mg/m², vincristine 1.4 mg/m² (maximum, 2 mg), and rituximab 375 mg/m² on day 1 and prednisone 100 mg once daily on days 1 to 5, for a total of 8 cycles. Pegfilgrastim was administered on day 2 of each cycle. Patients randomly assigned to arm B received extra intravenous...
rituximab 375 mg/m² on day 8 of the first 4 cycles (R-CHOP-14). Initially, inclusion was limited to elderly patients (age 66-80 years). In July 2009, the protocol was amended to also include patients aged 18 to 65 years. At the same time, because of the results of the RICOVER-60 trial, the number of CHOP-14 cycles for patients aged 66 to 80 years was reduced to 6, whereas the number of rituximab cycles was maintained at 8.² Details regarding prephase and supportive measures during treatment are provided in the Appendix (online only). Consolidation radiotherapy was not allowed.

Response at the end of induction treatment was assessed using PET-CT scans.¹⁴,¹⁵ Patients with progressive disease on CT scan after 4 cycles went off protocol. The interim PET scan after 4 cycles was performed for observational purposes only. All PET-CT scans were centrally reviewed by the HOVON Imaging Group according to standard procedures as previously described¹⁶ using Deauville score (DS) for visual assessment.¹⁵ Scores of 1 to 3 were interpreted as complete metabolic response, and scores of 4 to 5 were consistent with partial metabolic response or progressive disease. CT scans of neck, chest, abdomen, and pelvis were required at 6, 12, 18, and 24 months after completion of induction treatment. Severity of adverse events was defined according to the National Cancer Institute Common Terminology Criteria for Adverse Events (version 3.0).

Sample Size Calculation and Statistical Analysis

This trial was designed to compare CR rates on induction treatment between R-CHOP-14 and RR-CHOP-14 (first randomization; R1) and compare failure-free survival (FFS) from second randomization (R2) between no further treatment and rituximab maintenance. The sample size for R1 was 575 patients, accrued over 5 years, with a power of 86% to detect an improvement in CR rate from 77% to 87%. Additional sample size calculation details are provided in the Appendix. The primary end point for R1 was CR on induction. Logistic regression analysis with adjustment for age group (18-65 v ≥ 66-80 years) and age-adjusted IPI risk factors (0 v 1 v 2 v 3; categorical) was applied for the primary analysis, and odds ratios and 95% CIs were determined, with P values < .05 considered statistically significant. Secondary end points were best response on protocol treatment, adverse events, FFS, progression-free survival (FFS), and OS from R1 and disease-free survival (DFS) from CR. For the survival end points, the hazard ratios (HRs) and 95% CIs were determined using univariable and multivariable Cox regression analyses. Kaplan-Meier curves by treatment arm were generated to illustrate survival.

All analyses were performed according to the intention-to-treat (ITT) principle. However, patients initially randomly assigned but considered ineligible in retrospect based on information that should have been available before random assignment were excluded from the respective analyses (modified ITT). The proportion of patients with specific adverse events was compared between arms post hoc using the χ² test or Fisher’s exact test, whichever was appropriate. All reported P values are 2 sided and were not adjusted for multiple testing. Additional details on statistical methods and survival end point definitions are provided in the Appendix.

RESULTS

Study Patients

Between November 14, 2007, and April 6, 2012, 600 patients were enrolled. Twenty-six patients (R-CHOP-14 arm, n = 14; RR-CHOP-14 arm, n = 12) were considered ineligible in hindsight and excluded from all analyses because of diagnosis other than DLBCL at study entry according to local pathology (n = 12), stage I disease (n = 4), absence of age-adjusted IPI risk factors (n = 4), CNS involvement (n = 2), absence of measurable disease (n = 1), heart disease (n = 1), administrative error (n = 1), or missing data (n = 1). Of 574 patients included in the modified ITT analysis, 286 individuals were allocated to the R-CHOP-14 arm and 288 were assigned to the RR-CHOP-14 arm (Fig 1). Central pathology review was available for 522 (91%) of 574 eligible patients, and diagnosis of CD20+ DLBCL according to the 2008 WHO classification was confirmed for 492 (94%) of 522 patients. Baseline characteristics of patients were well balanced between arms (Table 1; Appendix Table A1, online only).

Treatment

At least 6 cycles were received by 269 (94%) of 286 patients in the R-CHOP-14 arm and 261 (91%) of 288 patients in the RR-CHOP-14 arm; 151 patients (53%) received 7 to 8 cycles of R-CHOP-14, compared with 158 (55%) in the RR-CHOP-14 arm (Fig 1). The median total dose received and median relative dose-intensities achieved for cyclophosphamide (98%) and doxorubicin (98%) were similar in the R-CHOP-14 and RR-CHOP-14 arms. However, for vincristine, in patients aged 66 to 80 years, the median total dose and median relative dose-intensities were 12.0 versus 10.0 mg (P = .015) and 92% versus 85% (P = .083) for the R-CHOP-14 and RR-CHOP-14 arms, respectively.

Efficacy Outcomes

There was no statistically significant difference in the primary end point of CR rate on induction between the 2 treatment arms. CR was achieved in 254 patients (89%) in the R-CHOP-14 arm and in 249 (86%) in the RR-CHOP-14 arm (HR, 0.82; 95% CI, 0.50 to 1.36; P = .44; adjusted for age and age-adjusted IPI score). Also, CR rates for patients aged < 66 years (90% v 85%) and patients aged ≥ 66 years (88% v 88%) were not different per treatment arm.

After a median follow-up of 92 months (range, 1-131 months) in the 364 patients still alive, the median FFS and
median PFS were not reached in the R-CHOP-14 arm and were both 101 months in the RR-CHOP-14 arm, and the median DFS and OS had not been reached in either arm. The 3-year FFS rate was 74% (95% CI, 68% to 78%) in the R-CHOP-14 arm versus 69% (95% CI, 63% to 74%) in the RR-CHOP-14 arm (HR, 1.26; 95% CI, 0.98 to 1.61; P = .07; adjusted for age group and age-adjusted IPI score; Fig 2A); FFS rates at 5 years were 68% (95% CI, 62% to 73%) and 62% (95% CI, 56% to 67%), respectively. PFS at 3 years was 74% (95% CI, 69% to 79%)

FIG 1. CONSORT diagram of induction treatment of patients with diffuse large B-cell lymphoma in the HOVON-84 non-Hodgkin lymphoma trial by treatment arm. CR, complete remission; R1, induction randomization; R2, maintenance randomization; R-CHOP, rituximab on day 1 of each cycle plus cyclophosphamide, doxorubicin, vincristine, and prednisone (arm A); RR-CHOP, rituximab on days 1 and 8 of first 4 cycles and day 1 of remaining cycles plus cyclophosphamide, doxorubicin, vincristine, prednisone (arm B).

Abbreviations: BM, bone marrow; DLBCL, diffuse large B-cell lymphoma; IPI, International Prognostic Index; LDH, lactate dehydrogenase; R-CHOP, rituximab on day 1 of each cycle plus cyclophosphamide, doxorubicin, vincristine, and prednisone (arm A); RR-CHOP, rituximab on days 1 and 8 of first 4 cycles and day 1 of remaining cycles plus cyclophosphamide, doxorubicin, vincristine, and prednisone (arm B); SH, single hit; ULN, upper limit of normal.

aAppendix Table A1.
bBased on standard Hans criteria.
cAccording to WHO classification 2016; now classified as high grade B-cell lymphoma with MYC and BCL2 and/or BCL6 rearrangements.

in the R-CHOP-14 arm versus 71% (95% CI, 66% to 76%) in the RR-CHOP-14 arm (HR, 1.20; 95% CI, 0.94 to 1.55; P = .15; adjusted for age group and age-adjusted IPI score; Fig 2B); the 5-year PFS rates were 69% (95% CI, 63% to 74%) and 64% (95% CI, 58% to 69%), respectively. Among patients who had achieved CR on protocol treatment, the 3-year DFS rate from date of CR was 81% (95% CI, 76% to 85%) in the R-CHOP-14 arm versus 76% (95% CI, 70% to 81%) in the RR-CHOP-14 arm (HR, 1.24; 95% CI, 0.93 to 1.65; P = .15; adjusted for age group and age-adjusted IPI score; Fig 2C); the 5-year DFS rates were 75% (95% CI, 69% to 80%) and 70% (95% CI, 64% to 75%), respectively. OS at 3 years was 81% (95% CI, 76% to 85%) in the R-CHOP-14 arm versus 76% (95% CI, 70% to 80%) in the RR-CHOP-14 arm (HR, 1.27; 95% CI, 0.97 to 1.67; P = .09; adjusted for age group and age-adjusted IPI score; Fig 2D); the 5-year OS rates were 77% (95% CI, 71% to 81%) and 69% (95% CI, 63% to 74%), respectively.

A total of 210 patients died, 96 in the R-CHOP-14 arm (lymphoma related, n = 41; treatment related, n = 9; intercurrent death, n = 8; secondary malignancies, n = 11; other reasons, n = 15; and unknown causes, n = 12) and 114 in the RR-CHOP-14 arm (lymphoma related, n = 56; treatment related, n = 10; intercurrent death, n = 10; secondary malignancies, n = 11; other reasons, n = 11; and unknown causes, n = 16).

Planned subgroup analyses showed that the impact of RR-CHOP-14 versus R-CHOP-14 on FFS, PFS, DFS, and OS was not different between subgroups of age (18-65 v 66-80 years), sex (male v female), or age-adjusted IPI score (low v low-intermediate v high-intermediate v high). Post hoc analyses showed similar results for subgroups according to DLBCL phenotype. Figure 3 and Appendix Figures A1 and A2 (online only) show the Kaplan-Meier PFS curves for these subgroups.

Results of the multivariable analyses of individual prognostic factors for the survival end points FFS, PFS, and OS are listed in Table 2 (and for DFS in Appendix Table A2, online only). The HRs for both treatment arms were similar compared with those in the analyses with adjustment for only age group and age-adjusted IPI score, confirming that survival was not improved in either subgroup in the RR-CHOP-14 arm. The only statistically significant prognostic factor was age 66 to 80 years.

PET-CT Assessment

PET-CT scans were visually assessed using the 5-point DS; DSs 1 to 3 were regarded as negative and DSs 4 to 5 as positive. A total of 496 end-of-treatment (EOT) PET scans were centrally reviewed. In 417 patients (84%), the EOT PET-CT scans were negative, and 79 patients (16%) had positive EOT PET scans. The estimated 2-year PFS rate in patients with EOT PET–positive scans was 46%
(95% CI, 36% to 57%) versus 88% (95% CI, 85% to 92%) in those with EOT PET–negative scans (P = .001). The 2-year OS rate was 58% (95% CI, 47% to 69%) for patients with EOT PET–positive scans and 94% (95% CI, 91% to 96%) for those with EOT PET–negative scans. Corresponding positive and negative predictive values for 2-year PFS were 53% (95% CI, 42% to 64%) and 89% (95% CI, 85% to 91%) for EOT PET scans, respectively.

### Rituximab Pharmacokinetics

Rituximab trough serum levels increased after each subsequent treatment cycle during the first 4 cycles and reached a plateau at cycles 5 to 8 in both treatment arms. Rituximab trough serum levels were systematically higher in the RR-CHOP-14–treated patients than in R-CHOP–treated patients (Appendix Figure A3, online only).

### Adverse Events

We analyzed safety for all patients who received at least 1 administration of study treatment. The proportion of patients with at least 1 adverse or serious adverse event did not differ between the R-CHOP-14 and RR-CHOP-14 arms. The most common grade 3 and 4 adverse events were cytopenias and infections (Table 3). During the first 4 cycles, patients between ages 66 and 80 years experienced significantly more toxicity in the RR-CHOP-14 arm, especially neutropenia and infections (Table 4).

Seventeen grade 5 adverse events were reported during induction, 9 in the R-CHOP-14 arm and 8 in the RR-CHOP-14 arm. The main cause of death was infection (4 patients in each arm). Other causes of death in the R-CHOP-14 arm were small-bowel perforation (n = 2), sudden death (n = 2), and progressive multifocal
leukoencephalopathy \((n = 1)\). In the RR-CHOP-14 arm, other causes of death were myocardial infarction \((n = 1)\), GI bleeding \((n = 1)\), small-bowel perforation \((n = 1)\), and cardiac arrhythmia \((n = 1)\).

**DISCUSSION**

The primary objective of achieving a significantly superior CR rate with RR-CHOP-14 treatment as compared with standard R-CHOP-14 treatment was not met. RR-CHOP-14 treatment also did not improve FFS, PFS, DFS, or OS. In DLBCL, rapid tumor control is critical to improve outcome by avoiding development of refractory disease on or after R-CHOP, because patients with refractory disease have poor prognosis.17 Several phase II studies have explored optimization of rituximab for the treatment of DLBCL. In the DENSE-R-CHOP-14 trial, early dose-intensification of rituximab in combination with R-CHOP-14 was tested in 124 elderly patients with DLBCL.17 In this study, 4 additional rituximab administrations were added during the first 3 weeks. Compared with a historical control population (RICOVER-60 population), no differences in outcome were

NOTE. Data are No. of patients (%) with an event. Patients could have the same type of event more than once.

Abbreviations: R-CHOP, rituximab on day 1 of each cycle plus cyclophosphamide, doxorubicin, vincristine, and prednisone (arm A); RR-CHOP, rituximab on days 1 and 8 of first 4 cycles and day 1 of remaining cycles plus cyclophosphamide, doxorubicin, vincristine, and prednisone (arm B). of R-CHOP was investigated in 189 elderly patients with DLBCL. Compared with the RICOVER-60 population, survival outcome was not significantly better for the complete study population, and subgroup analysis showed that patients with high-intermediate and high IPI scores had higher CR/CRu rates and better 3-year PFS (71% v 59%) and OS (80% v 67%) rates. Elderly male patients showed a significantly faster rituximab clearance than elderly female patients, resulting in a shorter rituximab serum elimination half-life, lower serum levels, and shorter rituximab exposure times. Because in the RICOVER-60 study elderly male patients seemed to benefit to a lesser extent from addition of rituximab to CHOP than elderly female patients, an increased dose of 500 mg/m² of rituximab for male patients and the standard dose of 375 mg/ m² for female patients were investigated in 271 elderly patients with DLBCL in the SEXIE-R-CHOP-14 study. No survival differences were found, and the authors concluded that the increased rituximab dose may have abrogated the negative effect in elderly male patients. These phase II studies in elderly patients with DLBCL supported the notion that patients with DLBCL with poor prognosis would be most likely to benefit from adapted rituximab schedules. In our study, trough rituximab levels were indeed consistently higher during the first 4 cycles in the RR-CHOP-14 arm than in the R-CHOP-14 arm, and they remained higher during further treatment. However, this did not translate into better short- or long-term outcome for the complete study population. Also, exploratory subgroup analyses for different age groups, age-adjusted IPI risk groups, and sexes could not identify any subgroup that might benefit from rituximab intensification. Our randomized phase III study differs in some essential aspects from the phase II studies. The study populations were not comparable; in our study, both young and elderly patients with DLBCL were observed for the whole population. Subgroup analysis revealed that patients with high-intermediate and high IPI scores had higher CR/CRu rates after rituximab intensification, but this did not translate into better survival outcome. A high rate of grade 3 and 4 infectious complications was reported, which improved after mandatory prophylaxis with acyclovir and cotrimoxazole was instituted. In the SMARTE-R-CHOP-14 study, a prolonged exposure time of rituximab using a loading schedule of 2 rituximab administrations before the first CHOP cycle and 3 additional rituximab administrations after completion...
included, whereas the phase II studies included elderly patients only and included a broader spectrum of aggressive B-cell lymphoma diagnoses. In our phase III study, staging and response evaluation was based on PET-CT, whereas it was based on CT scanning only in the phase II studies. Lastly, the schedules for rituximab intensification differed to some extent. However, from these studies, it may be concluded that dose-intensification within a standard R-CHOP regimen is insufficient to improve outcome for patients with DLBCL. Tout et al has demonstrated that rituximab exposure is influenced by baseline metabolic tumor volume (MTV) and suggest that outcome might improve when the rituximab dose is individualized according to the MTV. This interesting hypothesis needs to be confirmed in a prospective trial.

For the past 2 decades, R-CHOP has remained the standard treatment for previously untreated DLBCL, and it has proven exceedingly difficult to improve on this baseline. To date, neither next-generation anti-CD20 monoclonal antibodies, such as obinutuzumab or ofatumumab, nor approaches adding targeted therapy based on molecular subtypes of DLBCL, such as bortezomib, ibrutinib, or lenalidomide in ABC/non-GCB subgroups, have proven successful. More recent developments in chemoimmunotherapy using antibody-drug conjugates (eg, polatuzumab vedotin), bispecific antibodies (eg, anti-CD3 \(*\) anti-CD20), immune checkpoint inhibitors, and CAR T-cell therapy may reveal new opportunities, and novel insights into DLBCL biology may provide essential information for meaningful patient selection for such treatments. Our phase III study shows that early rituximab intensification in patients with untreated DLBCL during R-CHOP-14 does not improve outcome.

Prephase Treatment and Supportive Measures During R-CHOP-14 Treatment

Prephase treatment. A prephase treatment before the start of study treatment was mandatory in all elderly patients (age 66-80 years) and was left at the discretion of the treating physician in young patients (age 18-65 years). The prephase treatment consisted of a 5-day course of 100 mg of prednisone once daily.

Prednisone tapering. A gradual reduction of the prednisone dose was recommended to prevent marked fatigue after prompt discontinuation of prednisone. Prednisone 50 mg could be administered on day 6, 25 mg on day 7, and 10 mg on day 8. For patients complaining of fatigue after tapering of prednisone, hydrocortisone 20 mg orally in the morning and 10 mg orally at 1200 was recommended.

Intrathecal prophylaxis for CNS relapse was at the discretion of the treating physician. The dose should have been adapted if the creatinine clearance was decreased.

Sample Size Calculation

The sample size was calculated to have a sufficient number of patients available for the second randomization (R2); thereafter, the statistical power for the first randomization (R1) was determined. To detect with 80% power an improvement in failure-free survival (FFS) from R2 with a hazard ratio (HR) of 0.60 (2-sided significance level, \( \alpha = 0.05 \)), 126 events were required. Assuming a proportional hazard for young versus elderly patients of 0.62, an accrual period of 5 years, and 2 years of follow-up after the last patient was included in the maintenance randomization, this would require 395 patients (young, \( n = 174 \); elderly, \( n = 221 \)). Therefore, 575 patients should be included in this trial, resulting in a power of 86% to detect an improvement in complete remission (CR) rate from 77% to 87%.

Statistical Methods

The primary end point for R1 was CR on induction. Patient treatment was considered a success if CR was achieved during or after induction treatment. All other patient treatments were considered a failure. Logistic regression analysis with adjustment for age group (18-65 vs. 66-80 years) and age-adjusted International Prognostic Index (IPI) score (0 v 1 v 2 v 3 v categorical) was applied for the primary analysis, and odds ratios and 95% CIs were determined, with \( P \) values < .05 considered statistically significant.

Secondary end points were best response on protocol treatment, adverse events, FFS, progression-free survival (PFS) and overall survival (OS) from R1, and disease-free survival (DFS) from CR. DFS was defined as time from R1 to no CR on protocol, relapse, or death, whichever came first. PFS was calculated from R1 to progression, relapse, or death, whichever came first. OS was determined from R1 to death resulting from any cause. Patients still alive at last contact were censored. DFS was measured from date of CR to relapse or death, whichever came first.

The proportion of patients with specific adverse events was compared between arms post hoc using the \( \chi^2 \) test or Fisher’s exact test, whichever was appropriate.

For the survival end points, the HRs and 95% CIs were determined using univariable and multivariable Cox regression analyses. Multivariable Cox regression analysis was primarily aimed at evaluating the impact of adjustment on the HRs and 95% CIs of treatment arms, rather than at evaluating the prognostic value of individual covariates, and included: treatment arm, age (18-65 vs. 66-80 years), sex (male vs female), age-adjusted IPI stage (low v low-intermediate v high-intermediate v high; continuous), WHO performance (0 v 1 v 2; continuous), lactate dehydrogenase (normal v elevated); B symptoms (no vs yes), bulky mass (no vs yes), and bone marrow involvement (no vs yes), as specified in the statistical analysis plan. Because the number of patients with missing data was low (ie, 3 of 574 eligible patients [1%]), the multivariable Cox regression analyses were restricted to patients with complete data. Kaplan-Meier curves by treatment arm were generated to illustrate survival.

All analyses were performed according the intention-to-treat (ITT) principle. However, patients initially randomly assigned but considered ineligible in retrospect based on information that should have been available before random assignment were excluded from the respective analyses (modified ITT).

Two interim analyses were planned after the inclusion of 200 and 400 evaluable patients, primarily to guard against unfavorable results in the experimental arm, and the results were presented confidentially to an independent data and safety monitoring board. All reported \( P \) values are 2 sided and were not adjusted for multiple testing.

Rituximab Pharmacokinetics

Rituximab pharmacokinetics were evaluated in 6 patients in the R-CHOP-14 arm and 4 patients in the RR-CHOP-14 (R-CHOP-14 with intensification of rituximab in the first 4 cycles) arm during the induction phase. Thirty to 60 minutes before each rituximab infusion, 5 mL of blood was drawn, and samples were centrifuged at 1,000 for 10 minutes at room temperature and stored at −20°C until shipping on dry ice for analysis. Rituximab serum levels were measured by enzyme-linked immunosorbent assay at Xendo Laboratories (Groningen, the Netherlands).

Participating Hospitals and Principal Investigators
