Erythropoietin Induces Neovascularization and Improves Cardiac Function in Rats With Heart Failure After Myocardial Infarction

OBJECTIVES
We assessed the effects of erythropoietin (EPO) treatment in a rat model of post-myocardial infarction (MI) heart failure.

BACKGROUND
Erythropoietin, traditionally known as a hematopoietic hormone, has been linked to neovascularization. Whereas administration of EPO acutely after MI reduces infarct size and improves cardiac function, its role in the failing heart is unknown.

METHODS
Rats underwent coronary ligation or sham surgery. Rats with MI were randomly assigned to: untreated (MI), a single bolus of EPO immediately after MI induction (MI-EPO–early), EPO treatment immediately after MI and once every three weeks (MI-EPO–early+late), and EPO treatment starting three weeks after induction of MI, once every three weeks (MI-EPO–late). After nine weeks, hemodynamics, infarct size, myosin heavy chain (MHC) isoforms, myocyte hypertrophy, and capillary density were measured.

RESULTS
Erythropoietin treatment started immediately after MI (MI-EPO–early and MI-EPO–early+late) resulted in a 23% to 30% reduction in infarct size (p < 0.01) and, accordingly, hemodynamic improvement. Erythropoietin treatment, started three weeks after MI (MI-EPO–late), did not affect infarct size, but resulted in an improved cardiac performance, reflected by a 34% reduction in left ventricular end-diastolic pressure (p < 0.01), and 46% decrease in atrial natriuretic peptide levels (p < 0.05). The improved cardiac function was accompanied by an increased capillary density (p < 0.01), an increased capillary-to-myocyte ratio (p < 0.05), and a partial reversal of beta-MHC (p < 0.05) in all treated groups.

CONCLUSIONS
In addition to its effect on infarct size reduction, EPO treatment improves cardiac function in a rat model of post-MI heart failure. This observation may be explained by neovascularization, associated with an increased alpha-MHC expression. (J Am Coll Cardiol 2005;46:125–33) © 2005 by the American College of Cardiology Foundation
leads to a time-related and infarct size-related ventricular dilatation and heart failure (17). We hypothesized that EPO treatment initiated after heart failure development (three weeks after induction of MI) would improve cardiac performance, possibly by increasing capillary density. To distinguish the acute effects of EPO (i.e., infarct size reduction) from its effects in CHF, we studied two additional groups. In one group we administered only a single dose of EPO immediately after MI, and in a second group we administered EPO immediately after MI and continued EPO treatment during the experiment.

METHODS

Animals. We used male Sprague Dawley rats weighing 270 to 330 g (Harlan, Zeist, the Netherlands). Animals were fed ad libitum, and housed in groups of four to five rats, according to institutional rules with 12:12 h light-dark cycles. The experimental protocol was approved by the Animal Ethical Committee of the University of Groningen.

Design of the study. Rats were either subjected to left coronary artery ligation (n = 85) or sham surgery (n = 8). Rats with MI were randomized to one of four groups; untreated (MI) or three different treatment strategies with EPO: a single bolus of EPO immediately after ligation (MI-EPO–early); EPO treatment directly after ligation and once every three weeks (MI-EPO–late); and EPO treatment starting three weeks after ligation, once every three weeks (MI-EPO–early).

EPO: a single bolus of EPO immediately after ligation

Abbreviations and Acronyms

CHF = chronic heart failure
dLVP = developed left ventricular pressure
EPO = erythropoietin
LV = left ventricle/ventricular
LVEDP = left ventricular end-diastolic pressure
LVSP = left ventricular systolic pressure
MHC = myosin heavy chain
MI = myocardial infarction
N-ANP = N-terminal atrial natriuretic peptide

Erythropoietin Attenuates Heart Failure

miwave puberty during the experiment. We administered EPO immediately after MI and continued the dose of EPO immediately after MI, and in a second group we administered EPO immediately after MI and continued EPO treatment during the experiment.

EPO treatment initiated after heart failure development (three weeks after induction of MI) would improve cardiac performance, possibly by increasing capillary density. To distinguish the acute effects of EPO (i.e., infarct size reduction) from its effects in CHF, we studied two additional groups. In one group we administered only a single dose of EPO immediately after MI, and in a second group we administered EPO immediately after MI and continued EPO treatment during the experiment.

METHODS

Animals. We used male Sprague Dawley rats weighing 270 to 330 g (Harlan, Zeist, the Netherlands). Animals were fed ad libitum, and housed in groups of four to five rats, according to institutional rules with 12:12 h light-dark cycles. The experimental protocol was approved by the Animal Ethical Committee of the University of Groningen.

Design of the study. Rats were either subjected to left coronary artery ligation (n = 85) or sham surgery (n = 8). Rats with MI were randomized to one of four groups; untreated (MI) or three different treatment strategies with EPO: a single bolus of EPO immediately after ligation (MI-EPO–early); EPO treatment directly after ligation and once every three weeks (MI-EPO–early+late); and EPO treatment starting three weeks after ligation, once every three weeks (MI-EPO–late).

Erythropoietin (Darbeepoetin-alpha; Aranesp, Amgen Inc., Thousand Oaks, California) was administered intraperitoneally at a dose of 40 µg/kg, which equals 8,000 U/kg recombinant human EPO (Amgen Inc.) and is in close range of known dosages for organ protection (11,12,18). Hematocrit was measured at baseline and at week one, three, four, six, and nine after surgery. Persons blinded to the treatment groups performed the analysis of samples obtained from the experiments.

MI model. This model has been described previously (16). Briefly, rats were anesthetized with 2% isoflurane in 1.0 l oxygen/min. After intubation, the rats were put on a mechanical ventilator (frequency 90/min), and a left-side thoracotomy was performed. Myocardial infarction was induced by ligating the proximal portion of the left coronary artery, beneath the left atrial appendage. In sham-operated rats, the same surgery was performed, without ligating the suture.

Hemodynamic measurements. After nine weeks, rats were anesthetized as described above. Micropipette pressure transducer (Millar Instruments Inc., Houston, Texas) was inserted into the LV cavity via the right carotid artery. After a 3-min period of stabilization, heart rate, left ventricular systolic pressure (LVSP), left ventricular end-diastolic pressure (LVEDP), and developed left ventricular pressure (dLVP = LVSP – LVEDP) were measured. As indexes of contractility and relaxation, the maximal rates of increase and decrease in LV pressure (+dP/dt max and −dP/dt max) were determined. The catheter was retracted into the aortic arch, and arterial systolic and diastolic blood pressures were recorded.

Plasma N-terminal atrial natriuretic peptide (N-ANP) levels. Arterial blood was collected after nine weeks, anticoagulated with EDTA, and plasma was stored at −80°C until assayed. Plasma N-ANP was measured by a commercially available radioimmunoassay (Biotop, Oulu, Finland) as described previously (19).

Infarct size and LV hypertrophy. After hemodynamic measurements, hearts were rapidly excised and weighed. Mid-papillary slices were prepared for immunohistochemistry. Slices were fixed in 4% paraformaldehyde and paraffin-embedded. Infarct size was determined by planimetry at mid-ventricular levels in transverse slices on picrosirius red/fast green-stained sections. Infarct size was expressed as the percentage of scar length to total LV circumference, as described previously (20,21). Deparaffinized 5-µm thick sections were stained with a Gomori's silver staining, in order to visualize individual myocytes in the viable LV wall, the area with the most pronounced underperfusion (22). Using image analysis (Zeiss KS 400, Jena, Germany), concentric myocyte hypertrophy in the viable LV wall, remote from the infarcted area, was measured as the cross-sectional area of transversally cut myocytes showing a nucleus. Myocyte density was calculated as the average number of myocytes per tissue area. In each stained section, measurements were averaged from three different counting fields (± 75 myocytes per heart).

Myosin heavy chain (MHC) isof orm analysis. Samples of the LV (not infarct area), were frozen in liquid nitrogen and stored at −80°C. The freeze-dried samples were dissolved in a buffer, and gel electrophoresis was performed as described previously (23). Samples (0.5 µg) were run at constant current (24 mA) for 5 h. Silver staining of the gels and laser scanning densitometry was performed to identify differences in myosin isof orm composition (i.e., alpha-MHC and beta-MHC).

Capillary density. To visualize capillaries in the myocardium in the same area as used for the measurements of the myocyte size, endothelial cells were stained with biotin-labeled Lectin GSL (1:100; Sigma-Aldrich, St. Louis, Missouri), as previously described (16). Because lectins stain not only capillaries but also other vessels, a size criterion of
10 μm was used to exclude small arterioles and venules. Image analysis (Image Pro-plus version 4.5, Media Cybernetics Inc., Silver Spring, Maryland) was used to measure capillary density, calculated as the number of capillaries per tissue area. The measured total tissue area was corrected for the remaining interstitial space. Actual neovascularization was derived from an increased capillary-to-myocyte ratio, which has been calculated as capillary density divided by myocyte density (24).

**Statistical analysis.** Data are presented as mean ± SEM. Statistical analysis between groups was performed by one-way analysis of variance. When a statistically significant difference was detected, a Fisher protected LSD post-hoc analysis was performed. Correlation analysis was performed with Pearson’s correlation tests. Differences were considered significant at p < 0.05.

**RESULTS**

**General.** Overall mortality after MI was 41%. Mortality occurred only in the first 24 h after induction of MI. There were no statistically significant differences in mortality between the four groups (MI: 50%, MI-EPO–early: 40%; MI-EPO–late: 32%, and MI-EPO–early+late: 41%; p = 0.54). No mortality was observed in sham-operated rats. At baseline, no differences in body weight were observed (data not shown). General characteristics after nine weeks are shown in Table 1. Body weight was comparable among the five groups. Among groups with MI, systolic blood pressure was significantly lower only in MI and MI-EPO–early compared to sham; p < 0.01. Systolic blood pressure was significantly higher in MI-EPO–late and MI-EPO–early+late compared to MI group (p < 0.05). No significant differences were observed in heart rate and diastolic blood pressure, although there was a trend towards higher diastolic blood pressure in the groups repeatedly treated with EPO (MI-EPO–late and MI-EPO–early+late). The changes of the hematocrit throughout the experiment are also shown in Table 1. After nine weeks, hematocrit values were significantly elevated in the MI-EPO–late and MI-EPO–early+late compared to other groups.

**Infarct size.** Left ventricular infarct size (percent of LV) was comparable between MI and MI-EPO–late, 43% and 41%, respectively (p = 0.60; Table 1). Treatment with EPO immediately after coronary artery ligation reduced infarct size by 30% in MI-EPO–early and by 23% in MI-EPO–early+late groups (both p < 0.01 vs. MI; Table 1).

**Hemodynamic measurements.** Hemodynamic data obtained nine weeks after surgery are summarized in Figure 1. The LVSP and dLVP were both clearly diminished in MI compared to sham-operated rats (p < 0.01 for both); MI-EPO–late and MI-EPO–early+late showed a significantly higher LVSP and dLVP, compared to MI (all p < 0.05). One single bolus of EPO immediately after ligation (MI-EPO–early) did not result in a significantly improved LVSP or dLVP (Figs. 1A and 1B).

The LVEDP was elevated in MI compared to sham-operated rats (21 ± 3 mm Hg vs. 8 ± 1 mm Hg; p < 0.01). Importantly, EPO treatment started three weeks after MI (MI-EPO–late), resulted in a 34% decrease in LVEDP, compared to MI (p < 0.01), despite similar infarct sizes. Immediate treatment with EPO after induction of MI (MI-EPO–early and MI-EPO–early+late) led to a 27% and 38% reduction in LVEDP, respectively, compared to MI group (p < 0.05 and p < 0.01; Fig. 1C).

Myocardial contractility (−dP/dt_{max}) and myocardial relaxation (−dP/dt_{max}) were both impaired in MI compared to the sham group (both p < 0.01); MI-EPO–late and MI-EPO–early+late showed an improved contractility and relaxation compared to MI (all p < 0.05). In contrast, when only one single bolus of EPO was admin-

Data are presented as mean ± SEM. *p < 0.05; †p < 0.01 vs. sham; ‡p < 0.05; §p < 0.01 vs. MI.

BW = body weight; DBP = diastolic blood pressure; EPO = erythropoietin; LV = left ventricle; MI = myocardial infarction; n = number of animals; SBP = systolic blood pressure.
istered immediately after MI (MI-EPO–early), contractility and relaxation were not significantly improved compared to MI (Figs. 1D and 1E).

**N-terminal ANP levels.** Figure 2 shows that plasma N-ANP levels were three-fold increased in MI group (p < 0.01 vs. sham-operated animals). Furthermore, N-ANP levels were significantly reduced in the MI-EPO–late and MI-EPO–early/late groups (p < 0.05 and p < 0.01 vs. MI), returning to sham values (both p = NS vs. sham). The MI-EPO–early group showed a trend towards lower N-ANP levels (p = 0.07 vs. MI).

**Organ weights and LV hypertrophy.** As shown in Table 1, the ratios of heart weight to body weight and of lung weight to body weight were significantly increased in the MI compared to the sham-operated group (both p < 0.01). Lung weight to body weight (an indirect expression of the LVEDP and, thus, severity of heart failure) was significantly reduced in all EPO treatment groups (all p < 0.01 vs. MI). A trend towards lower heart weight to body weight compared to MI was observed in MI-EPO–late and MI-EPO–early+late groups. Left ventricular hypertrophy was further studied by histological analysis. Representative photomicro-

**Figure 1.** Effects of myocardial infarction (MI) and erythropoietin (EPO) treatment on hemodynamic parameters. dLVP = developed left ventricular pressure; LVEDP = left ventricular end-diastolic pressure; LVSP = left ventricular systolic pressure; +dP/dt\text{max} = maximal rate of increase; −dP/dt\text{max} = decrease of ventricular pressure. *p < 0.05 vs. MI; **p < 0.01 vs. MI; #p < 0.01 vs. sham.

**Figure 2.** Plasma N-terminal atrial natriuretic peptide (N-terminal ANP) levels. EPO = erythropoietin. *p < 0.05 vs. myocardial infarction (MI); **p < 0.01 vs. MI; #p < 0.01 vs. sham. 
graphs of Gomori-stained sections of the viable LV free wall are shown in Figure 3A. Myocardial infarction resulted in a 35% increase in myocyte cross-sectional area, compared to sham (p < 0.05). All EPO-treated groups showed a trend towards a smaller myocyte cross-sectional area, although this did not reach statistical significance (Fig. 3B).

**Differences in MHC isoform composition.** Relative proportion of cardiac alpha-MHC and beta-MHC were compared in LV protein samples between the five different groups. Myocardial infarction resulted in a more than five-fold increase in expression of beta-MHC, compared to sham-operated rats (p < 0.01); EPO treatment in all three groups reduced the expression of beta-MHC by 26% to 31%, compared to MI (p < 0.05; Fig. 4).

**Capillary density.** Capillaries stained with lectin were clearly discernable in the myocardium. Figure 5A shows representative photomicrographs of the five different groups. Capillary density was significantly reduced in the MI group compared to the sham group (p < 0.01); EPO treatment in all three groups prevented the decrease in capillary density after induction of MI and restored it to sham values, as shown in Figure 5B (p = NS vs. sham). Furthermore, in the MI-EPO–late and MI-EPO–early+late groups, we observed a 39% and 48% increase in capillary-to-myocyte ratio, respectively (p < 0.05 and p < 0.01 vs. MI), whereas MI-EPO–early showed a clear trend (p = 0.05 vs. MI) towards an increased capillary-to-myocyte ratio (Fig. 5C).

In order to relate LV functional parameters through an MHC shift to increased capillarization, correlations were determined. We observed a strong correlation between capillary density and beta-MHC expression (r = −0.47, p < 0.01) and subsequently between beta-MHC expression and cardiac contractility and relaxation, r = −0.52 and r = 0.61, respectively (both p < 0.01). Furthermore, capillary density was correlated with myocardial contractility (r = 0.32) and relaxation (r = −0.37; both p < 0.05).

**DISCUSSION**

In the present study, the effects of EPO treatment in a rat model of post-MI heart failure were examined. To our knowledge, this study shows for the first time that EPO treatment initiated three weeks after induction of MI results in an improved cardiac function, as shown by a 17% increase of dLVP at 34% reduction in LVEDP and a 46% decrease in N-ANP levels. Furthermore, our data indicate that EPO
restores capillary density to sham levels and increases the capillary-to-myocyte ratio, indicating neovascularization. **Myocardial structure and cardiac function.** Previous studies already revealed that EPO has ancillary properties besides hematopoiesis. One of the first studies on EPO in the heart showed that EPO injected intraperitoneally for seven days reduced cardiomyocyte loss by 50% after ischemia-reperfusion injury (25). These observations have been confirmed by others. Parsa et al. (12) showed a 25% reduction in infarct size after four days of permanent occlusion of the left circumflex coronary artery in rabbits. A single dose of EPO at the onset of MI reduced infarct size, which was accompanied by reductions in LV size and an improved LV ejection fraction, measured by echocardiography.

**Figure 4.** Effects of myocardial infarction (MI) and erythropoietin (EPO) treatment on beta-myosin heavy chain (MHC) protein expression as a percentage of total MHC expression. *p < 0.05 vs. MI; **p < 0.01 vs. sham.

graphy, during eight weeks follow-up (26). Our results are in line with these findings; one single dose of EPO administered immediately after induction of MI reduces infarct size by 30% and improves hemodynamics. Mechanisms behind this acute protective effect of EPO may be related to its antiapoptotic effect. We and others (11,12,15,26) showed that, in the acute phase of MI, EPO markedly prevents cardiac cells from undergoing programmed cell death (apoptosis). After MI, apoptosis is first observed in endothelial cells of small coronary vessels, spreading to the surrounding cardiomyocytes (27). Because the EPO receptor is predominately expressed on endothelial cells, preventing apoptosis in these cells may rescue the underlying myocardium (13). Recently it has been postulated that cardiac fibroblasts may also play a role in the cardioprotective effects of EPO (15).

Although a single dose of EPO clearly improves cardiac performance, prolonged EPO treatment (MI-EPO–early+late) was associated with a further restoration of cardiac function. Mechanisms involved in this process are most likely distinct from its acute cardioprotective effect. This is clearly demonstrated by the finding that EPO treatment, initiated three weeks after MI, although not reducing infarct size, significantly improves cardiac function, reflected by a 17% increase of dLVP at 34% decrease in LVEDP, and restoring N-ANP levels to sham values. Because the effect of EPO treatment in this group could not be explained by infarct size reduction, other properties of EPO should be considered to elucidate the observed beneficial effects of EPO in heart failure.

Neovascularization. Erythropoietin has been shown to possess proangiogenic properties. As discussed above, the EPO receptor is expressed on endothelial cells, and EPO has been shown to stimulate the proliferation and migration of endothelial cells in vitro (6). Additional experiments in chick embryos demonstrated that EPO treatment results in angiogenesis similar to other well-known angiogenic cytokines (6). Furthermore, EPO induces vascular sprouting in a rat aortic ring model (28). In human cultured myocardial tissue, EPO stimulates capillary outgrowth comparable to vascular endothelial growth factor (7). In a rodent model of hind-limb ischemia, EPO increases capillary density 1.6-fold (29). In a rat model of chronic renal failure characterized by LV hypertrophy and capillary deficiency, EPO treatment results only in a small nonsignificant increase in cardiac capillary density (30). In a rat model of stroke, EPO treatment, initiated 24 h after infarction, enhances angiogenesis and improves neurological function, while it does not significantly influence infarct size. Our results suggest a similar effect of EPO in the heart. We find that EPO treatment restores capillary density to sham values and increases capillary-to-myocyte ratio, indicating actual capillary growth (24), which is more pronounced in the groups with prolonged EPO treatment.

To study the functional consequences of increased capillarization, we examined the expression of different MHC isoforms in heart tissue. Cardiomyocytes express both fast alpha-MHC and slow beta-MHC isoforms, which differ on the basis of ATPase activity. Recently it has been shown that expression of a small amount of alpha-MHC (∼12%) in rat cardiomyocytes significantly increases power output, indicating that a small shift in MHC composition, as we found in all EPO-treated groups, may improve contractility (31). Increased capillary density was significantly correlated with the percentage of beta-MHC isoform as well as with myocardial function (+dP/dt max and −dP/dt max), providing a link between neovascularization and functional effects of EPO.

The mechanism behind the effect of EPO on new blood vessel formation in the heart remains unknown. In general, stimulation of in situ endothelial cell proliferation or bone-marrow–derived endothelial progenitor cells might play a role. Previous work showed that EPO effectively increases the amount of circulating endothelial progenitor cells (32), and significantly induces angiogenesis (29). Future experiments are needed to delineate the mechanism of EPO-stimulated capillary growth.

Hematopoietic effect. Another important property of EPO that might be involved in the cardioprotective effect observed in our study is its hematopoietic effect. Human recombinant EPO increases the number of reticulocytes after administration to rats after 3 to 4 days with a maximum after 8 to 11 days (33). In our study, we observed significant hematocrit elevation one week after a single dose of EPO. In the groups treated with multiple EPO doses, hematocrit remained significantly elevated throughout the experiment. The beneficial effects seen in these groups might, thus, in part, be explained on the basis of increased oxygen–carrying capacity of blood. However, the effects of higher red blood cell mass on oxygen delivery is not straightforward, because elevated hematocrit may down-regulate nitric oxide synthesis and, thus, impair tissue blood flow (34). In the clinical setting, increasing the number of red blood cell mass by blood transfusion has been reported to improve outcome in elderly patients after acute MI (35). Nevertheless, this beneficial effect is only seen in patients with hematocrit <33%. On the other hand, reduction in the infarct size observed in the early treated groups could not be attributed to the hematopoietic effect of EPO, because cell death and MI expansion occur mainly during the first three days after ischemic insult (26) and, thus, before significant hematocrit elevation.

Conversely, an increase in hematocrit may itself tend to deteriorate myocardial perfusion through adverse rheological effects. Elevated hematocrit levels (up to 80%) in polyglobular mice, overexpressing EPO, enlarge cerebral infarct volumes and leukocyte infiltration after permanent occlusion of middle cerebral artery (36). Furthermore, EPO administration and consequent higher hematocrit has been associated with other adverse cardiovascular effects. Therapeutic levels of EPO may cause higher incidence of thrombosis (37) and could lead to blood pressure elevation (38). In the present study, rats repeatedly treated with EPO had a
higher systolic blood pressure. This increase might be related to the improved cardiac function; however, the systolic blood pressure remained below the values observed in the sham-operated group.

**Clinical implications.** In clinical settings, EPO treatment has already been used to correct anemia in patients with CHF. Anemia is frequently observed in patients with CHF and related to increased morbidity and mortality (39,40). Furthermore, not only anemia, but also elevated endogenous EPO levels, are independently associated with an impaired outcome in CHF (41). Normalization of hemoglobin levels in mildly anemic patients with CHF has a positive effect on LV ejection fraction (42) and peak VO₂ (43). In addition to correction of anemia, other nonhematopoietic effects of EPO may play a role in the improvement observed in patients with CHF treated with EPO.

Besides the treatment of anemia, EPO is currently under investigation for its neuroprotective properties. In the first clinical, randomized, proof-of-concept trial, EPO was given to patients with ischemic stroke (44); EPO administration in high doses (entire dose 100,000 IU given in three days) proved to be both safe and beneficial. Patients randomized to the EPO group showed significant improvement in clinical outcome parameters and a trend towards smaller infarct sizes.

However, chronic therapy with EPO is also associated with adverse effects related to hematocrit elevation, such as hypertension and thromboembolic complications. This could be overcome by using a lower dose of EPO, as shown by Bahlmann et al. (45). In this study, a low dose of darbepoetin (0.1 µg/kg/week) rendered tissue protection in the kidneys even without raising hematocrit levels. The recently discovered nonhematopoietic derivates of EPO retaining tissue protection but without the undesired effects on hematopoiesis may become another possibility for chronic administration (46).

**Study limitations.** Several limitations of the present study have to be acknowledged. Although a clear increase in capillary density and capillary-to-myocyte ratio was observed, the improvement of cardiac function might also be related to other effects of EPO treatment. Because we did not perform sequential measurements of cardiac function, further studies would be needed to specifically denote the time-dependent effect of EPO treatment on attenuation of heart failure development.

We did not measure the direct myocardial perfusion, and, therefore, functional evidence of an improved perfusion remains unclear. However, we observed a clear correlation between capillary density and beta-MHC expression and cardiac function. Furthermore, we used the Fisher LSD post-hoc statistical test for analyzing our data, which does not control for multiple comparisons.

**Conclusions.** In summary, the present study demonstrates that EPO treatment in a rat model of heart failure improves cardiac function beyond its effect on infarct size reduction. This improvement could be explained by the increased capillary density and capillary-to-myocyte ratio, indicating formation of new blood vessels.
