Applications of the Poincaré–Hopf Theorem: Epidemic Models and Lotka–Volterra Systems

Mengbin Ye, Member, IEEE, Ji Liu, Member, IEEE, Brian D. O. Anderson, Life Fellow, IEEE, and Ming Cao, Senior Member, IEEE

Abstract—This article focuses on properties of equilibria and their associated regions of attraction for continuous-time nonlinear dynamical systems. The classical Poincaré–Hopf theorem is used to derive a general result providing a sufficient condition for the system to have a unique equilibrium. The condition involves the Jacobian of the system at possible equilibria and ensures that the system is in fact locally exponentially stable. We apply this result to the susceptible–infected–susceptible (SIS) networked epidemic model, and a generalized Lotka–Volterra system. We use the result further to extend the SIS model via the introduction of decentralized feedback controllers, which significantly change the system dynamics, rendering existing Lyapunov-based approaches invalid. Using the Poincaré–Hopf approach, we identify a necessary and sufficient condition, under which the controlled SIS system has a unique nonzero equilibrium (a diseased steady state), and monotone systems theory is used to show that this nonzero equilibrium is attractive for all nonzero initial conditions. A counterpart condition for the existence of a unique equilibrium for a nonlinear discrete-time dynamical system is also presented.

Index Terms—Complex networks, differential topology, feedback control, monotone systems.

I. INTRODUCTION

M ANY dynamical processes in the natural sciences can be studied as continuous-time systems of the form

\[ \dot{x} = f(x) \]  

(1)

where \( f(\cdot) \) is a suitably smooth nonlinear vector-valued function, and \( x = [x_1, \ldots, x_n]^{\top} \) represents a vector of \( n \geq 1 \) biological, chemical, or physical variables. In the course of conducting analysis on such models, it is often of interest to characterize the equilibria of (1), including the number, stability properties, and associated regions of attraction. In context, there is usually (but not always) an equilibrium at \( x = 0_n \), where \( 0_n \) is the \( n \)-dimensional vector of all zeros, reflecting the situation where the modeled process has ceased completely, and we call it the trivial equilibrium. There is obvious interest to determine if there exist nontrivial equilibria of (1), and how many. One particular focus may be to determine conditions on \( f \) such that (1) has a unique nontrivial equilibrium (if, in fact, any such conditions exist).

Suppose that one has an intuition perhaps obtained from extensive simulations that the particular system of interest (1) has a unique nontrivial equilibrium, i.e., \( x^* \). Then, the existence and uniqueness of \( x^* \) might be proved by analysis using algebraic calculations involving the particular \( f(\cdot) \) of interest. If \( f(\cdot) \) is highly nonlinear, or \( n \) is large (e.g., (1) is modeling a complex networked system), a proof of the uniqueness of \( x^* \) reliant on the algebraic form of the specific \( f \) may be extremely complicated. Some systems admit Lyapunov functions that simultaneously establish that \( x^* \) is unique and that it is globally attractive [1]; this approach was also applied to several classes of coupled systems of differential equations over networks [2]. However, such an approach is not applicable for systems, including those in the natural sciences, which exhibit limit cycles or chaos [3], [4].

Moreover, one may wish to modify some system (1) by introducing additional nonlinearities and obtain a new system \( \dot{x} = f(x) \). For example, and as we shall do in this article, one may insert a feedback control \( u(x) \) to ensure that the closed-loop system \( \dot{x} = f(x) + u(x) \) achieves some control objective. Alternatively, \( f(\cdot) \) may have been obtained by making idealized assumptions of the process being modeled, and one wishes to relax or change these assumptions to better reflect the real world, resulting in a new system. Suppose that one were again interested in determining whether \( \dot{x} = f(x) \) had a unique
nontrivial equilibrium, i.e., \( x^* \). A logical approach would be to extend the analysis method for the unique equilibrium \( x^* \) for (1) to consider \( \bar{f}(\cdot) \). However, approaches relying on algebraic calculations using the specific \( f(\cdot) \) may not be general enough to guarantee successful adaptation for the various modified \( \bar{f}(x) \). Moreover, a Lyapunov function that works for (1) may not work with \( \bar{x} = \bar{f}(x) \), and finding a new Lyapunov function may prove challenging.

Motivated by the above observations, this article seeks to identify sufficient conditions for a general system of the form of (1) to have a unique equilibrium, involving as few calculations of the specific \( f(\cdot) \) as possible. Once the existence of a unique equilibrium has been established, Lyapunov or other dynamical systems theory tools (as will be the case in this article) can be used to identify regions of convergence.

### A. Contributions of This Article

There are several contributions of this article, which we now detail. First, we use the classical Poincaré–Hopf theorem [5] from a differential topology to derive a sufficient condition that simultaneously establishes the existence and uniqueness of the equilibrium for a general nonlinear system (1), and that the equilibrium is locally exponentially stable. One can consider our result to be a specialization of the Poincaré–Hopf theorem. No conclusions are drawn on the existence or nonexistence of limit cycles or chaotic behavior, though additional tools described later in this article can establish such conclusions. Some existing works have used the Poincaré–Hopf theorem to count equilibria, but typically focus on a specific system of interest within a specific applications domain (including sometimes static as opposed to dynamical systems) [6]–[14]. We then apply the result to three example systems from the natural sciences. While these example systems are all positive systems, i.e., \( x_i(t) \geq 0 \) for all \( i = 1, \ldots, n \) and \( t \geq 0 \), our result can be applied to many general nonlinear systems, with no restriction on the signs of the states.

Key to our approach is to check whether the Jacobian of \( f(\cdot) \) in (1) at every possible equilibrium is stable, though no \textit{a priori} knowledge is needed that an equilibrium even exists. While computation of the Jacobian does require some knowledge of the algebraic form of \( f(\cdot) \), we have found that in applying our approach to established models of biological systems, the level of complexity in calculations based on the specific algebraic form of \( f(\cdot) \) is significantly reduced.

The first example system we study is the deterministic susceptible–infected–susceptible (SIS) network model for an epidemic spreading process. There is a well-known necessary and sufficient condition for the SIS model to have a unique nontrivial endemic equilibrium (which corresponds to the disease being present in the network) in addition to the trivial healthy equilibrium (which corresponds to a disease-free network) [15]–[19]. We show how the existence and uniqueness of this endemic equilibrium, based on this known condition, can be easily established using our aforementioned specialization of the Poincaré–Hopf theorem.

Next, we introduce decentralized feedback controllers into the SIS network model as our second example, with the objective of globally stabilizing the controlled SIS network to the healthy equilibrium. The equations for the controlled system are no longer quadratic, as they were for the uncontrolled system, and existing approaches, including those based on Lyapunov theory, cannot be extended to consider the controlled system. In contrast, we show that the Poincaré–Hopf approach admits a direct and rather straightforward extension from the uncontrolled SIS system to the controlled SIS system. This allows us to prove that the controlled system has a unique endemic equilibrium, which is locally exponentially stable, if and only if the uncontrolled system has a unique endemic equilibrium. We then appeal to results from monotone systems theory [20], [21] to prove that the unique endemic equilibrium is in fact asymptotically stable for all feasible nonzero initial conditions. Our analysis covers a broad class of controllers, significantly extending a specific case in [22].

Last, we apply the specialization of the Poincaré–Hopf theorem to generalized nonlinear Lotka–Volterra systems first studied in [23], which are popular for modeling the interaction of populations of biological species [3]. We use the Poincaré–Hopf approach to relax the sufficient condition of [23] for ensuring the existence of a unique nontrivial equilibrium (and establish that it is locally exponentially stable). Limit cycles and chaotic behavior, arising in many Lotka–Volterra systems, are not ruled out. Taking the same condition as in [23], we then recover the global convergence result of [23] but with a simplified argument.

Naturally, one may also wish to consider nonlinear discrete-time systems \( x(k) = G(x(k)), k = 0, 1, \ldots \). It turns out that there is a counterpart condition for establishing existence and uniqueness of the equilibrium, which was first reported in [24], and is established using the Lefschetz–Hopf theorem [25]. In this article, we recall the discrete-time result of [24] and its application to the DeGroot–Friedkin model of a social network [26] and compare it against the result we derived for (1).

A preliminary version of this article was published in the 21st IFAC World Congress [27], covering limited results on the controlled SIS network model. This article provides more material on the Poincaré–Hopf theorem specialization and its motivations, development of monotone systems theory, results on generalized Lotka–Volterra systems, and discussion of the discrete-time counterpart.

The rest of this article is structured as follows. In Section II, we provide relevant mathematical notation and preliminaries, and an explicit motivating example with the network SIS model. Section III introduces the Poincaré–Hopf theorem and the specialization for application to general nonlinear systems. This specialization is applied to the network SIS model in Section IV and Lotka–Volterra models in Section V. The discrete-time result is covered in Section VI. Section VII concludes this article.

### II. BACKGROUND AND PRELIMINARIES

#### A. Notation

To begin, we establish some mathematical notation. The \( n \times n \) column vector of all ones and zeros is given by \( 1_n \) and \( 0_n \), respectively. The \( n \times n \) identity and \( n \times m \) zero matrices are given by \( I_n \) and \( 0_{n \times m} \), respectively. For a vector \( a \) and matrix \( A \), we denote the \( i \)th entry of \( a \) and \((i, j)\)th entry of \( A \) as \( a_i \) and \( a_{ij} \), respectively.
respectively. For any two vectors \( a, b \in \mathbb{R}^n \), we write \( a \geq b \) and \( a > b \) if \( a_i \geq b_i \) and \( a_i > b_i \), respectively, for all \( i \in \{1, \ldots, n\} \). A real matrix \( A \in \mathbb{R}^{n \times m} \) is said to be nonnegative or positive if \( A \geq 0 \) or \( A > 0 \), respectively.

For a real square matrix \( M \) with spectrum \( \sigma(M) \), we use
\[
\rho(M) = \max \{ |\lambda| : \lambda \in \sigma(M) \}
\]
and
\[
s(M) = \max \{ \Re(\lambda) : \lambda \in \sigma(M) \}
\]
to denote the spectral radius of \( M \) and the largest real part among the eigenvalues of \( M \), respectively. A matrix \( M \) is said to be Hurwitz if \( s(M) < 0 \).

The Euclidean norm is \( \| \cdot \| \), and the \( (m-1) \)-dimensional sphere embedded in \( \mathbb{R}^m \) is denoted by \( S^{m-1} \). For a set \( M \) with boundary, we denote the boundary as \( \partial M \), and the interior \( \text{Int}(M) = M \setminus \partial M \). We define the set
\[
\Xi_n = \{ x \in \mathbb{R}^n : 0 \leq x_i \leq 1, i \in \{1, \ldots, n\} \}
\]
and denote by \( \mathbb{R}^n_0 = \{ x \in \mathbb{R}^n : x_i \geq 0, i = 1, \ldots, n \} \) and \( \mathbb{R}^n_{>0} = \{ x \in \mathbb{R}^n : x_i > 0, i = 1, \ldots, n \} \) the positive orthant and the interior of the positive orthant, respectively.

### B. Graph Theory

For a directed graph \( G = (\mathcal{V}, \mathcal{E}, A) \), \( \mathcal{V} = \{1, \ldots, n\} \) is the set of vertices (or nodes). The set of directed edges is given by \( \mathcal{E} \subseteq \mathcal{V} \times \mathcal{V} \) and the edge \((i, j)\) is an arc that is incoming with respect to \( j \) and outgoing with respect to \( i \). The matrix \( A \) is defined such that \((i, j) \in \mathcal{E} \) if and only if \( a_{ij} \neq 0 \). We will sometimes write “the matrix \( A \) associated with \( G \)” or write \( G[A] \) to represent \( G = (\mathcal{V}, \mathcal{E}, A) \). We define the neighbor set of \( i \) as \( N_i = \{ j : e_{ji} \in \mathcal{E} \} \). A directed path is a sequence of edges \((p_1, p_2), (p_2, p_3), \ldots \), where \( p_i \in \mathcal{V} \) are distinct and \( (p_1, p_{i+1}) \in \mathcal{E} \). A graph \( G[A] \) is strongly connected if and only if there is a path from every node to every other node, which is equivalent to \( A \) being irreducible [28].

### C. Motivating Example: The Network SIS Model

To more explicitly motivate the application of the Poincaré–Hopf theorem, we introduce the first of several examples studied in this article, viz., the network SIS model [15], which is a fundamental model in the deterministic epidemic modeling literature. To remain concise, we do not discuss the modeling derivations, for which details are found in, e.g., [15] and [29].

For some disease of interest, it is assumed that each individual is either Infected (I) with the disease, or is Susceptible (S) but not Infected, or is recovered (R). An individual \( i \) is said to be nonnegative or positive if
\[
0 \leq x_i \leq 1,
\]
and denote by \( \mathbb{R}^n_0 = \{ x \in \mathbb{R}^n : x_i \geq 0, i = 1, \ldots, n \} \) and \( \mathbb{R}^n_{>0} = \{ x \in \mathbb{R}^n : x_i > 0, i = 1, \ldots, n \} \) the positive orthant and the interior of the positive orthant, respectively.

### III. Application of the Poincaré–Hopf Theorem for a Class of Nonlinear Systems

Before introducing the main result of this section, which is one of the key novel contributions of this article, we first detail the notion of a tangent cone [30], and define what is meant by a vector field “pointing inward” to a set \( \mathcal{M} \), and introduce the relevant aspects of differential topology.

Let the distance between a point \( x \in \mathbb{R}^n \) and a compact set \( Q \subseteq \mathbb{R}^n \) be defined as
\[
dist(x, Q) = \inf_{y \in Q} \| x - y \|.
\]
The tangent cone to \( Q \) at \( x \) is the set
\[
\mathcal{Z}_Q(x) = \left\{ z \in \mathbb{R}^n : \lim_{h \to 0} \frac{\dist(x + h z, Q)}{h} = 0 \right\}.
\]
If \( Q \) has a boundary \( \partial Q \), the one-sided limit \( \lim_{h \to 0^-} \) is used in (6) for \( x \in \partial Q \) (see [31], Appendix D). This article will consider (1) on an \( m \)-dimensional compact manifold \( M \subset \mathbb{R}^n \),
with \( m \leq n \). It is important to distinguish the dimension of \( \mathcal{M} \), viz., \( m \), from the dimension of the ambient space \( \mathbb{R}^n \) in which \( \mathcal{M} \) is embedded, viz., \( n \). A natural choice is to embed \( \mathcal{M} \) into a space of the dimension of \( f \) in (1), and which we will assume henceforth. For example, if \( \mathcal{M} \) is a ball, then clearly \( m = n \). If, however, \( \mathcal{M} \) is the \((n-1)\)-sphere embedded in \( \mathbb{R}^n \), then \( m = n - 1 < n \).

We now relate \( Z_{\mathcal{M}}(x) \) to the tangent space of \( \mathcal{M} \) at \( x \), denoted by \( T_x \mathcal{M} \subseteq \mathbb{R}^m \). For all \( y \notin \mathcal{M} \), one has \( Z_{\mathcal{M}}(y) = \emptyset \). However, \( Z_{\mathcal{M}}(x) = T_x \mathcal{M} \subseteq \mathbb{R}^m \) for all \( x \in \text{Int}(\mathcal{M}) \). That is, the tangent cone at any point \( x \) in the interior of \( \mathcal{M} \) is equal to the tangent space of \( \mathcal{M} \) at the same point, being a Euclidean space with the same dimension as \( \mathcal{M} \). If \( \mathcal{M} \) has a boundary, then \( Z_{\mathcal{M}}(x) \subset T_x \mathcal{M} \) for all \( x \in \partial \mathcal{M} \). More specifically, the tangent cone on a boundary point is a subset of the tangent space, comprised of vectors whose directions “point inward” to \( \mathcal{M} \) (as detailed below). These conclusions are intuitive from a geometric viewpoint and proved (with additional details) in the arXiv version of this article [31, Appendix D]. Armed with this knowledge, we now recall the following classical result and a definition that will be useful in the following.

**Proposition 2 (Nagumo’s theorem [30, Th. 3.1]):** Consider the system in (1), and suppose that it has a globally unique solution for every initial condition. Let \( \mathcal{M} \subseteq \mathbb{R}^n \) be an \( m \)-dimensional compact and smooth manifold, with \( m \leq n \). Then, \( \mathcal{M} \) is positively invariant for the system if and only if \( f(x) \in Z_{\mathcal{M}}(x) \) for all \( x \in \mathcal{M} \).

Let \( f : U \rightarrow \mathbb{R}^n \) be a vector-valued function, \( U \subseteq \mathbb{R}^n \). On a manifold \( \mathcal{M} \) of appropriate dimension, a vector field can be represented by \( f \), as the mapping \( f : \mathcal{M} \rightarrow \mathcal{T}\mathcal{M} \), where \( \mathcal{M} \subseteq U \) and \( \mathcal{T}\mathcal{M} \subseteq \mathbb{R}^n \).

**Definition 1 (Pointing inward):** Consider a vector field defined by \( f : \mathcal{M} \rightarrow \mathcal{T}\mathcal{M} \), where \( \mathcal{M} \subseteq \mathbb{R}^n \) is an \( m \)-dimensional compact manifold with boundary \( \partial \mathcal{M} \), and \( m \leq n \). The vector field is said to point inward to \( \mathcal{M} \) at a point \( x \in \mathcal{M} \) if

\[
\{ f(x) \in Z_{\mathcal{M}}(x) \} \backslash \partial Z_{\mathcal{M}}(x) \quad (7)
\]

A vector field defined by a vector-valued function \( g \) is said to point outward if \( f = -g \) satisfies (7). Since the vector field is represented by \( f \) on \( \mathcal{M} \), the phrases “the vector field points inward” and “\( f \) points inward” will in this article connote the same thing, as defined in Definition 1.

**A. Algebraic and Differential Topology**

We now introduce some definitions and concepts from topology and then recall the Poincaré–Hopf theorem. To stay focused on applications to existing models, we do not provide extensive details, which can be found in [5] and [32].

Consider a smooth map \( f : X \rightarrow Y \), where \( X \) and \( Y \) are manifolds. Then, associated with \( f \) at a point \( x \in X \) is a linear derivative mapping \( df_x : T_x X \rightarrow T_{f(x)} Y \), where \( T_x X \) and \( T_{f(x)} Y \) are the tangent space of \( X \) at \( x \in X \) and \( Y \) at \( y = f(x) \in Y \), respectively. If the manifold \( X \) locally at \( x \) looks like \( \mathbb{R}^m \), then \( df_x \) is simply the Jacobian of \( f \) evaluated at \( x \) in a local coordinate basis. Suppose that \( X \) and \( Y \) are of the same dimension. A point \( x \in X \) is called a regular point if \( df_x \) is nonsingular, and a point \( y \in Y \) is called a regular value if \( f^{-1}(y) \) contains only regular points.

Suppose further that \( X \) and \( Y \) are manifolds of the same dimension without boundary, with \( X \) compact and \( Y \) connected. The (Brouwer) degree of \( f \) at a regular value \( y \in Y \) is [5]

\[
\text{deg}(f, y) = \sum_{x \in f^{-1}(y)} \text{sign det}(df_x).
\]

Here, \( \text{det}(df_x) \) is the determinant of \( df_x \), and \( \text{sign det}(df_x) = \pm 1 \) is simply the sign of the determinant of \( df_x \) (note that \( y \) being a regular value implies \( df_x \) is nonsingular). Notice that \( \text{sign det}(df_x) = +1 \) or \(-1 \) according as \( df_x \) preserves or reverses orientation. Remarkably, \( \text{deg}(f, y) \) is independent of the choice of regular value \( y \) [5, Th. A], and we can thus write the left-hand side of (8) simply as \( \text{deg}(f) \).

A point \( x \in X \) is said to be a zero of \( f \) if \( f(x) = 0 \), and we say that a zero \( x \) is isolated if there exists an open ball around \( x \), which contains no other zeros. A zero \( x \) with nonsingular \( df_x \) is said to be nondegenerate, and nondegeneracy of \( df_x \) is a sufficient condition for \( x \) to be isolated. For an isolated zero \( x \) of \( f \), pick a closed ball \( D \) centered at \( x \) such that \( x \) is the only zero of \( f \) in \( D \). The index of \( x \), denoted \( \text{ind}_{x}(f) \), is defined to be the degree of the map

\[
u : \partial D \rightarrow S^{m-1}
\]

\[
z \mapsto \frac{f(z)}{\|f(z)\|}.
\]

If \( x \) is a nondegenerate zero, then \( \text{deg}(u) = \text{sign det}(df_x) \) (see [5, Lemma 4]).

Finally, for a topological space \( X \), we introduce the Euler characteristic \( \chi(X) \) [5], [32], an integer number associated\(^1\) with \( X \). A key property is that distortion or bending of \( X \) (specifically a homotopy) leaves the number invariant. Euler characteristics are known for a great many topological spaces.

While variations of the Poincaré–Hopf theorem exist, with subtle differences, we now state one which will be sufficient for our purposes.

**Proposition 3 (The Poincaré–Hopf theorem [5]):** Consider a smooth vector field on a compact \( m \)-dimensional manifold \( \mathcal{M} \), defined by the map \( f : \mathcal{M} \rightarrow \mathcal{T}\mathcal{M} \). If \( \mathcal{M} \) has a boundary \( \partial \mathcal{M} \), then \( f \) must point outward at every point on \( \partial \mathcal{M} \). Suppose that every zero \( x_i \in \mathcal{M} \) of \( f \) is nondegenerate. Then

\[
\sum_{i} \text{ind}_{x_i}(f) = \sum_{i} \text{sign det}(df_{x_i}) = \chi(\mathcal{M})
\]

where \( \chi(\mathcal{M}) \) is the Euler characteristic of \( \mathcal{M} \).

**B. Uniqueness of Equilibrium for General Nonlinear Systems**

A specialization of the Poincaré–Hopf theorem will now be presented, which will be applied to different established dynamical models in Sections IV and V.

---

\(^1\)While the Euler characteristic can be extended to noncompact \( X \), this article will only consider the Euler characteristic for compact \( X \).
We focus on the system (1) on contractible manifolds. A manifold \( M \) is contractible if it is homotopy equivalent to a single point, or roughly speaking, \( M \) can be continuously deformed and shrunk into a single point. Any compact and convex subset of \( \mathbb{R}^n \) is contractible, e.g., \( \Xi_n \) in (2). A contractible manifold \( M \) has Euler characteristic \( \chi(M) = 1 \). The following is one of the main novel contributions of this article.

**Theorem 1 (Unique equilibrium):** Consider the autonomous system

\[
\dot{x} = f(x) \tag{10}
\]

where \( f \) is smooth, and \( x \in \mathbb{R}^n \). Let \( M \subset \mathbb{R}^n \) be an \( m \)-dimensional compact, contractible, and smooth manifold with boundary \( \partial M \), and with \( m \leq n \). Suppose that \( M \) is positively invariant for (10), and furthermore, \( f \) points inward\(^2\) to \( M \) at every point \( x \in \partial M \). If \( df_x \) is Hurwitz for every \( x \in M \) satisfying \( f(x) = 0 \), then (10) has a unique equilibrium \( x^* \in \text{Int}(M) \). Moreover, \( x^* \) is locally exponentially stable.

**Proof:** The bulk of the proof focuses on establishing the properties of (10), which will allow the existence and uniqueness of the equilibrium \( x^* \) to be concluded from application of the Poincaré–Hopf theorem, viz., Proposition 3.

To begin, we need to connect the language of Proposition 3 to that of Theorem 1. First, recall the identification of the tangent cone for \( M \) immediately above Proposition 2. The theorem assumptions, in conjunction with Definition 1 and Proposition 2, imply that for all \( x \in M \), \( f(x) \) is in the tangent space \( T_xM \) of \( M \). In other words, \( f : M \to T\bar{M} \) defines a smooth vector field on \( M \), as required for Proposition 3. Thus, one can consider the system (10) in \( M \), or \( f \) as representing a smooth vector field on \( M \), and conceptually, we are discussing the same thing.

Note that \( \bar{x} \) is a zero of \( f \) if and only if \( x \) is a zero of \( -f \). In other words, the possibly empty set of zeros of \( f \) and \( -f \) are the same (at this stage, we have not established the existence of any zero \( \bar{x} \in M \)). Denote \( g = -f \) as a vector-valued function representing the “negative” vector field, i.e., at any \( x \), \( f(x) \) and \( g(x) \) point in the opposite direction.

For any square matrix \( A \), the product of its eigenvalues is equal to \( \det(A) \). Suppose that \( df_x \) is Hurwitz for some \( \bar{x} \in M \). Then, all eigenvalues of \( dg_{\bar{x}} = -df_{\bar{x}} \) have positive real part, and one has \( \det(dg_{\bar{x}}) > 0 \). For any \( \bar{x} \in M \) satisfying \( f(\bar{x}) = 0 \) and \( df_{\bar{x}} \) is Hurwitz, we, therefore, have \( \det(dg_{\bar{x}}) = +1 \), and \( dg_{\bar{x}} \) is orientation preserving.

We are now ready to apply Proposition 3 to the vector field \( g = -f \) on the manifold \( M \). We know that if \( \bar{x} \) is a zero of \( g \) (and if it exists), then it is nondegenerate by hypothesis, and thus, \( \det(dg_{\bar{x}}) = \pm 1 \). Now, the hypothesis that \( f \) points inwards at every \( x \in \partial M \) is equivalent to having the vector field \( g \) point outwards at every \( x \in \partial M \). Then, (9) yields

\[
\sum_i \text{sign} \det(dg_{\bar{x}_i}) = \chi(M) = 1 \tag{11}
\]

since \( M \) is contractible. Because \( \text{sign} \det(dg_{\bar{x}_i}) = \pm 1 \), there must be at least one zero of \( g \) contributing to the left-hand side of (11); we have established the existence of at least one isolated zero \( \bar{x}_1 \in M \). The hypothesis that \( df_{\bar{x}_i} \) is Hurwitz implies that \( \text{sign} \det(dg_{\bar{x}_i}) = +1 \) for every \( \bar{x}_i \), as established in the preceding paragraph. This immediately proves the uniqueness of \( \bar{x}_1 = x^* \). Recalling that the set of zeros of \( f \) and \( g = -f \) are the same establishes the theorem claim. Since \( df_{\bar{x}} \) is Hurwitz, the linearization theorem [33, Th. 5.41] establishes the local exponential stability of \( x^* \). Note that the analysis also tells us that \( x^* \in \text{Int}(M) \).

Since the Poincaré–Hopf theorem does not restrict the manifold in consideration to be in the positive orthant of \( \mathbb{R}^n \), Theorem 1 does not impose that the state of (10) satisfies \( x(t) \geq 0 \). Three system models in the natural sciences are subsequently considered, which are such that \( x(t) \in \mathbb{R}^n_{\geq 0} \). Similarly, other works discussed in Section I have applied the Poincaré–Hopf theorem to specific systems (as opposed to general systems in Theorem 1), and several systems are not restricted to \( \mathbb{R}^n_{\geq 0} \) (see, e.g., [6] and [10]). Identifying a suitable manifold \( M \) requires some knowledge of the specific system. For instance, if (10) has a trivial equilibrium, i.e., at the origin \( 0_n \), and one is interested using Theorem 1 to study a nontrivial equilibrium, then \( M \) cannot contain the origin.

**Remark 1:** Note that the wording chosen in the second to last sentence of the theorem statement is deliberate. For general nonlinear \( f \), it may not even be easy to establish the existence of an equilibrium \( \bar{x} \in M \), let alone whether \( \bar{x} \) is unique. Nonetheless, one does not require knowing the existence or otherwise of \( \bar{x} \) to evaluate \( df_{\bar{x}} \). Then, one can obtain an expression for \( df_{\bar{x}} \) (and perhaps determine whether it is Hurwitz) by leveraging the equality \( f(\bar{x}) = 0 \), even if existence of such a \( \bar{x} \) has not been established.

**Remark 2:** In [15, Lemma 4.1], it is shown by an application of Brouwer’s fixed-point theorem [34] that if the compact and convex set \( M \) is positively invariant for the system (10) and \( f \) is Lipschitz in \( M \), then there exists at least one equilibrium \( \bar{x} \in M \). However, unlike Theorem 1, the uniqueness of \( \bar{x} \) or any stability properties cannot be concluded. Moreover, Theorem 1 relaxes the requirement that \( M \) be convex, since a great number of contractible manifolds are nonconvex. For example, if there exists an \( x_0 \in M \) such that for all \( x \in M \) and \( t \in [0, 1] \), the point \( tx_0 + (1-t)x \in M \), then \( M \) is contractible; such an \( M \) is sometimes called a star domain.

**IV. Deterministic Network Models of Epidemics**

In this section, as a first illustration, we apply Theorem 1 to the familiar deterministic SIS network model introduced in Section II-C. We require some additional notation and existing linear algebra results.

A Metzler matrix is a matrix which has off-diagonal entries that are all nonnegative [28]. A matrix \( A \in \mathbb{R}^{n \times n} \) with all off-diagonal entries nonpositive is called an \( M \)-matrix if it can be written as \( A = sI_n - B \), with \( s > 0 \), \( B \succeq 0_{n \times n} \), and \( s \geq \rho(B) \) [28]. The following results on Metzler matrices and \( M \)-matrices will prove useful for later analysis.\(^3\)

\(^2\)This implies that (10) cannot have equilibria on the boundaries of \( M \).

\(^3\)Such matrices are related to “compartmental matrices” studied in models of chemical reaction systems, ecosystems, etc. [35].
**Lemma 1:** Let \( A \) be an irreducible Metzler matrix. Then, \( s(A) \) is a simple eigenvalue of \( A \), and there exists a unique (up to scalar multiple) vector \( x > 0_n \) such that \( Ax = s(A)x \). Let \( z \geq 0_n \) be a given nonzero vector. If \( Az \leq \lambda z \) for some scalar \( \lambda \), then \( s(A) \leq \lambda \), with equality if and only if \( Az = \lambda z \). If \( Az \geq \lambda z \) and \( Az \neq \lambda z \), for some scalar \( \lambda \), then \( s(A) > \lambda \).

The first half of the lemma is a direct consequence of the Perron–Frobenius theorem for nonnegative matrices [28, Th. 2.1.4]. The second part can be obtained from a straightforward application of [28, Th. 2.1.11].

**Lemma 2** (see [28, Th. 6.4.6]): Let \( R \in \mathbb{R}^{n \times n} \) have all off-diagonal entries nonpositive. Then, the following statements are equivalent:
1) \( R \) is an \( M \)-matrix,
2) the eigenvalues of \( R \) have nonnegative real parts.

**Lemma 3** (see [36, Th. 4.31]): Suppose that \( R \) is a singular \( M \)-matrix. If \( Q \) is a nonnegative diagonal matrix with at least one positive diagonal element, then the eigenvalues of \( R + Q \) have strictly positive real parts.

**A. Unique Endemic Equilibrium for the Network SIS Model**

To begin, notice from Proposition 1 that the matrix \(-D + B\) uniquely determines the equilibria and the convergence behavior of the SIS network system (4). We are interested in applying Theorem 1 for \( s(-D + B) > 0 \) to prove the system (4) has a unique endemic equilibrium \( x^* \in \text{Int}(\Xi_n) \). Later, we apply the same tool to prove a more powerful result on decentralized control of the SIS model, providing a further generalization of Proposition 1. First, we need to find a contractible manifold \( M \) for the system (4) with the property that at all points on the boundary \( \partial M \),

\[
f(x) = (-D + B - XB)x
\]

is pointing inward. We now identify one such \( M \).

Since \( B \) is nonnegative, \(-D + B\) is a Metzler matrix. Let \( \phi \triangleq s(-D + B) \), where \( y > 0_n \) satisfies \((-D + B)y = \phi y \) in accordance with Lemma 1. Without loss of generality, assume that \( \max_i y_i = 1 \). For a given \( \epsilon \in (0, 1) \), define the set

\[
M_{\epsilon} \triangleq \{ x : \epsilon y_i \leq x_i \leq 1, \forall i = 1, \ldots, n \}.
\]

The boundary \( \partial M_{\epsilon} \) is the union of the faces

\[
P_i = \{ x : x_i = \epsilon y_i, x_j \in [\epsilon y_j, 1] \forall j \neq i \}
\]

\[
Q_i = \{ x : x_i = 1, x_j \in [\epsilon y_j, 1] \forall j \neq i \}.
\]

Note that \( M_{\epsilon} \subset \Xi_n \) for all \( \epsilon \in (0, 1) \), where \( \Xi_n \) is given in (2). This manifold, and related manifolds, will be used in our application of Theorem 1. To this end, we state the following lemma, with the proof given in Appendix B.

**Lemma 4:** Consider the system (4), and suppose that \( G = (V, E, B) \) is strongly connected. Suppose further that \( \phi \triangleq s(-D + B) > 0 \). Then, there exists a sufficiently small \( \epsilon > 0 \) such that \( M_{\epsilon} \) in (13) and \( \text{Int}(M_{\epsilon}) \) are both positive invariant sets of (4), and

\[
eg e_i^\top \dot{x} < 0 \quad \forall x \in P_i, i = 1, \ldots, n
\]

\[
e_i^\top \dot{x} < 0 \quad \forall x \in Q_i, i = 1, \ldots, n
\]
theorems, the first being Theorem 2. Note that the statement of Theorem 2 does not present new insights, as the results are already known (see Proposition 1). (In fact, Theorem 2 only provides a local convergence result.) Rather, it is the proof technique of Theorem 2, utilizing Theorem 1, that is of interest, and also is crucial for subsequent extension that identifies an almost global region of attraction.

Theorem 2: Consider the system (4), and suppose that \( G = (V, E, B) \) is strongly connected, and \( s(-D + B) > 0 \). Let \( \Xi_n \) be defined in (2). Then, in addition to the healthy equilibrium \( \hat{0}_n \), (4) has a unique endemic equilibrium \( \hat{x} \), satisfying \( x^* \) locally exponentially stable.

Proof: Let \( M_\epsilon \) be defined as above for Theorem 2, for some sufficiently small \( \epsilon > 0 \). Lemma 4 implies that any nonzero equilibrium \( \hat{x} \) of (4) must satisfy \( \hat{x} \in \text{Int}(\Xi_n) \) and

\[
0_n = (-D + (I_n - \hat{X})B)\hat{x}.
\]

This implies that \( I_n - \hat{X} \) is a positive diagonal matrix, and because \( B \geq 0 \), \( I_n - \hat{X} \) is irreducible. Define for convenience \( F(x) \equiv D - (I_n - X)B \). Clearly, \( F(x) \forall x \in M_\epsilon \) has off-diagonal entries that are all nonpositive, and it follows that \( -F(x) \) is a Metzler matrix for any equilibrium \( x \in M_\epsilon \). Lemma 1 and (16) indicate that \( s(-F(\bar{x})) = 0 \), and we conclude using Lemma 2 that \( F(\bar{x}) \) is a singular irreducible \( M \)-matrix.

The Jacobian of \( f(\cdot) \) in (12) at \( x \in M_\epsilon \) is given by

\[
df_x = -f'(x) + \Delta(x)
\]

where \( \Delta(x) = \sum_{i=1}^{n}(\sum_{j=1}^{n}b_{ij}x_j)\epsilon_i \epsilon_j^\top \) is a diagonal matrix. Because \( B \) is irreducible, there exists, for all \( i = 1, \ldots, n \), a \( k_i \) such that \( b_{ik_i} > 0 \), which implies that for all \( x \in M_\epsilon \), there holds \( \sum_{j=1}^{n}b_{ij}x_j \geq b_{ik_i}x_{k_i} > 0 \). In other words, \( \Delta(x) \) is a positive diagonal matrix for all \( x \in M_\epsilon \). It follows immediately from Lemma 3 that \( F(x) + \Delta(x) \) is a nonsingular \( M \)-matrix, and all of its eigenvalues have strictly positive real parts. In other words, \( df_x \) is Hurwitz for all \( x \in M_\epsilon \) satisfying (16). Application of Theorem 1 establishes that there is, in fact, a unique equilibrium \( x^* \in \text{Int}(M_\epsilon) \), and \( x^* \) is locally exponentially stable.

Existing approaches for proving uniqueness of the endemic equilibrium center were briefly mentioned in the discussion below Proposition 1. In the next subsection, we will modify (4) via the introduction of decentralized nonlinear feedback controllers. As a consequence, the existing methods of analysis centered around Lyapunov functions and algebraic computations cannot be directly applied, since the system dynamics are significantly changed. On the other hand, we will show that the analysis method of Theorem 2, which exploits Theorem 1, can be easily extended to include decentralized feedback control, with virtually no change in the analysis complexity. After presenting our results on the controlled SIS network model in Section IV-B, we will provide a detailed comparison of the framework proposed in this article, against existing approaches.

B. Decentralized Feedback Control: Challenges and Benefits

Recall that \( s(-D + B) > 0 \) implies that the system in (4) will converge to the unique endemic equilibrium \( x^* \in \text{Int}(\Xi_n) \), as outlined in Proposition 1. Given the epidemic context, control strategies for the SIS networked system presented in (4) almost always have the objective of eliminating the endemic equilibrium by driving the state \( x(t) \) to the healthy equilibrium \( 0_n \), or at least reducing the infection level at the endemic equilibrium. We give a brief overview of some existing approaches and refer the reader to [29] for a survey.

The diagonal entry \( d_i > 0 \) of the diagonal matrix \( D \) represents the recovery rate of the population \( i \), while \( b_{ij} > 0 \) represents the infection rate from population \( j \in N_i \) to population \( i \). A common centralized approach is to formulate and solve an optimization problem to minimize (and possibly render negative) the value \( s(-D + B) \) by setting constant values for parameters \( d_i \) or \( b_{ij} \), perhaps with certain “budget” constraints [37], [38]. The approach can be made partially decentralized [39], [40]. A distributed method has been recently proposed, but requires a synchronized stopping time across the network and an additional consensus process to compute a piece of centralized information [41].

In contrast, we suppose that we can dynamically control (and in particular increase) the recovery rate at node \( i \), using a feedback controller. Specifically, we replace \( d_i \) in (3) with \( d_i(t) = d_i + u_i(t) \), where \( d_i > 0 \) is the constant base recovery rate\(^*\) intrinsic to population \( i \), and \( u_i(t) \) is the injected control input at node \( i \). We first give some assumptions on \( u_i(t) \), before providing motivation and explanation.

In this article, we consider the general class of decentralized local state feedback controllers of the form

\[
u_i(t) = h_i(x_i(t)) \tag{18}\]

where \( h_i : [0, 1] \rightarrow \mathbb{R}_{\geq 0} \) is bounded, smooth, and monotonically nondecreasing, satisfying \( h_i(0) = 0 \). We are motivated to consider (18) for practical reasons. The control effort \( u_i(t) = h_i(x_i(t)) \) may represent pharmaceutical interventions, drug medication, or additional hospital resources, which allow infected individuals to more rapidly recover from the disease. For instance, zinc supplements have been reported to decrease the period of infection for the common cold [42]. Assuming that \( h_i \geq 0 \) is nondecreasing in \( x_i \), yields an intuitive feedback control strategy: additional resources are introduced into node \( i \) to increase (or keep constant) the recovery rate \( d_i(t) \) as the infection proportion \( x_i(t) \) increases. For population \( i \), (18) only requires the local state information \( x_i(t) \), which has the advantage of decentralized implementation. This contrasts with many existing approaches, such as those described above, which require centralized design or implementation, including information regarding \( D \) and \( B \). The work [22] considers \( d_i \) of the special form \( h_i(x_i) = k_i x_i \), with \( k_i > 0 \) and \( d_i = 0 \).

The network dynamics become

\[
\dot{x}(t) = (-D - H(x(t)) + B - X(t)B)x(t) \tag{19}\]

where \( H(x(t)) = \text{diag}(h_1(x_1(t)), \ldots, h_n(x_n(t))) \) is a nonnegative diagonal matrix. Notice the right-hand side of the equation is, in general, no longer quadratic in \( x \). It is straightforward to verify that if \( x(0) \in \Xi_n \), then \( x(t) \in \Xi_n \) for all \( t \geq 0 \). In accordance with intuition, the following establishes that when

\(^*\)We have assumed that \( d_i > 0 \) to ensure consistency with (3).
$s(-D + B) \leq 0$, the controlled network system in (19) retains the convergence properties of the uncontrolled system in (4), as noted earlier in Proposition 1.

**Theorem 3:** Consider the system in (19), with $G = (\mathcal{V}, \mathcal{E}, B)$ strongly connected, and $\Xi_n$ defined in (2). Suppose that $s(-D + B) \leq 0$ and for all $i \in \mathcal{V}$, $h_i : [0, 1] \rightarrow \mathbb{R}_{\geq 0}$ is bounded, smooth, and monotonically nondecreasing, satisfying $h_i(0) = 0$. Then, $\Omega_0$ is the unique equilibrium of (19) in $\Xi_n$, and $\lim_{t \rightarrow \infty} x(t) = \Omega_0$ for all $x(0) \in \Xi_n$.

**Proof:** Suppose that $x^*$ is a nonzero equilibrium of (19). A simple adjustment to Lemma 4 yields that $\Omega_0 < x^* < 1_n$. If $s(-D + B) < 0$, then according to Lemma 2, $D - B$ is an irreducible $M$-matrix. Since $I_n - X^*$ is a strictly positive diagonal matrix, $s((I_n - X^*)B) < s(B)$ according to [28, Corollary 2.1.5]. Combining this with the fact that $H(x^*)$ is nonnegative diagonal, we can use Lemma 3 and the definition of an $M$-matrix at the start of Section IV to conclude that $D + H(x^*) - (I_n - X^*)B$ is an irreducible nonsingular $M$-matrix. However, the nonsingularity property contradicts the assumption that $x^* > \Omega_0$ satisfies $(D + H(x^*)) - (I_n - X^*)B)x^* = \Omega_0$, according to (19). Thus, there are no endemic equilibria when $s(-D + B) \leq 0$.

From (19), we obtain that $\dot{x} \leq \dot{y} = (-D + B)y$ where $I_n - X(t)$ is a diagonal matrix with diagonal entries in $[0, 1]$, and $H(x(t))$ is nonnegative. If $s(-D + B) < 0$, then $-D + B$ is Hurwitz, and initialising $\dot{y} = (-D + B)y$ with $y(0) = x(0)$ yields $\lim_{t \rightarrow \infty} x(t) = \Omega_0$. Convergence when $s(-D + B) = 0$ can be similarly argued.

The following theorem identifies the outcome of using (18) to control (19) when $s(-D + B) > 0$.

**Theorem 4:** Consider the system in (19), with $G = (\mathcal{V}, \mathcal{E}, B)$ strongly connected, and $\Xi_n$ defined in (2). Suppose that $s(-D + B) > 0$, and for all $i \in \mathcal{V}$, $h_i : [0, 1] \rightarrow \mathbb{R}_{\geq 0}$ is bounded, smooth, and monotonically nondecreasing, satisfying $h_i(0) = 0$. Then, we have the following.

1. In $\Xi_n$, (19) has two equilibria: $x = \Omega_0$, and a unique endemic equilibrium $x^* \in \text{Int}(\Xi_n)$, which is unstable and locally exponentially stable, respectively.

2. For all $x(0) \in \Xi_n \setminus \Omega_0$, there holds $\lim_{t \rightarrow \infty} x(t) = x^*$ exponentially fast.

**Remark 3:** Theorem 4 establishes two key properties of the SIS model under feedback control. Item 1 indicates that a stable healthy state cannot be achieved, and a unique endemic equilibrium $x^*$ that is locally exponentially stable continues to exist; it is impossible for the decentralized feedback control to globally stabilize the system to the healthy equilibrium. Item 2 establishes a large region of attraction of the endemic equilibrium. In the following, we will show that feedback control “improves” the limiting behavior: the controlled system converges to an endemic equilibrium that is closer to the origin than the endemic equilibrium of the uncontrolled system.

**Proof:** The proof consists of two parts. In Part 1, we establish the existence and uniqueness of the endemic equilibrium $x^* \in \text{Int}(\Xi_n)$, and the local stability properties of $x^*$ and $\Omega_0$. In Part 2, we establish the convergence to $x^*$.

**Part 1:** Under the theorem hypothesis, $H(x(t))$ is a nonnegative diagonal matrix. It can be shown that if $s(-D + B) > 0$, then Lemma 4 continues to hold when replacing (4) with (19). Only simply adjustments to the proof of Lemma 4 are needed, which we omit for brevity. To summarize, there exists a sufficiently small $\epsilon > 0$ such that $M_\epsilon$ in (13) and $\text{Int}(M_\epsilon)$ are both positive invariant sets of (19), and for every $x \in \partial M_\epsilon$,

$$f(x) = (-D - H(x) + B - XB)x$$

(20)

points inward to $M$. Similar to the discussion above Theorem 2, we can obtain from $M_\epsilon$ a smooth and compact manifold $M_\epsilon$, with the property that $f(x)$ in (20) also points inward for every $x \in \partial M_\epsilon$. Thus, both $M_\epsilon$ and $\text{Int}(M_\epsilon)$ are positive invariant sets of (19). Moreover, there exists a finite $\kappa$ such that for all $x(0) \in \partial \Xi_n \setminus \Omega_0$, there holds $x(\kappa) \in M_\epsilon$. This implies that any nonzero equilibrium of (19) must be in $\text{Int}(M_\epsilon) \subset \text{Int}(\Xi_n)$.

Now, suppose that $\hat{x} \in \text{Int}(M_\epsilon)$ is an equilibrium of (19). Then, $\hat{x}$ must satisfy $\Omega_0 < \hat{x} < 1_n$ and

$$\Omega_0 = (-D - H(\hat{x}) + (I_n - \hat{X})B)\hat{x}$$

(21)

This implies that $I_n - \hat{X}$ is a positive diagonal matrix, and because $B \geq 0_\mathcal{N} \times \mathcal{N}$ is irreducible, $(I_n - \hat{X})B$ is also an irreducible nonnegative matrix. Let us define for convenience $F(x) \triangleq D + H(x) - (I_n - X)B$. Obviously, $F(x)$ is a nonnegative diagonal matrix having off-diagonal entries that are all nonpositive, and it follows that $-F(\hat{x})$ is a Metzler matrix for any equilibrium $\hat{x} \in M_\epsilon$. Lemma 1 and (21) indicate that $s(-F(\hat{x})) = 0$, and as a consequence, we can use Lemma 2 to conclude that $F(\hat{x})$ is a singular irreducible $M$-matrix.

Define

$$\Gamma(x) = \text{diag} \left( \frac{\partial h_1}{\partial x_1}, \ldots, \frac{\partial h_n}{\partial x_n} \right)$$

(22)

and because $h_i$ is monotonically nondecreasing in $x_i$, $\Gamma(x)$ is a diagonal matrix for all $x \in M_\epsilon$. The Jacobian of (19) at a point $x \in M_\epsilon$ is given by

$$df_x = -D - H(x) + B - XB - \Delta(x) - \Gamma(x)$$

$$= -F(x) + \Delta(x) - \Gamma(x)$$

(23)

where $\Delta(x) = \sum_{i=1}^{n} \sum_{j=1}^{n} b_{ij} x_i x_j$, $e_i^T$ is a diagonal matrix. Because $B$ is irreducible, there exists for all $i = 1, \ldots, n$, a $k_i$ such that $b_{ik_i} > 0$. This implies that for all $x \in M_\epsilon$, there holds $\sum_{j=1}^{n} b_{ij} x_j \geq b_{ik_i} x_{k_i} > 0$. It follows that $\Delta(x)$ is a positive diagonal matrix for all $x \in M_\epsilon$. Lemma 3 establishes that $F(\hat{x}) + \Delta(\hat{x}) + \Gamma(\hat{x})$ is a nonsingular $M$-matrix, with eigenvalues having strictly positive real parts. This implies that $df_x$ is Hurwitz for all $\hat{x} \in M_\epsilon$ satisfying (21). Application of Theorem 1 establishes that there is in fact a unique equilibrium $x^* \in \text{Int}(M_\epsilon) \subset \text{Int}(\Xi_n)$, and $x^*$ is locally exponentially stable.

Consider now the healthy equilibrium $\Omega_0$. Notice that $df_\Omega_0 = -F(\Omega_0) = -D + B$. Since $s(-D + B) > 0$ by hypothesis, the linearization theorem [33, Th. 5.42] yields that $\Omega_0$ is an unstable equilibrium of (19).

**Part 2:** We established above that there exists a finite $\kappa$ such that $x(\kappa) \in M_\epsilon$ for all $x(0) \in \partial \Xi_n \setminus \Omega_0$. To complete the proof, we only need to show that $\lim_{t \rightarrow \infty} x(t) = x^*$ for all $x(0) \in \text{Int}(M_\epsilon)$. We shall use key results from the theory of
monic dynamical systems, the details of which are presented in Appendix A.

First, notice that $df_x$ in (23) is an irreducible matrix with all off-diagonal entries nonnegative for all $x \in \text{Int}(\mathcal{M}_e)$. Thus, (19) is an $\mathbb{R}^{n \times n}_{\geq 0}$ monotone system in $\text{Int}(\mathcal{M}_e)$ (see Lemma 8 in Appendix A, and use $P_n = I_n$). Since $x^*$ is the unique equilibrium of (19) in the open, bounded, and positive invariant set $\text{Int}(\mathcal{M}_e) \subset \mathbb{R}^{n}_{\geq 0}$, Proposition 4 in Appendix A yields $\lim_{t \to \infty} x(t) = x^*$ asymptotically$^5$ for all $x(0) \in \mathcal{M}_e$. It remains to prove that the convergence is exponentially fast.

Since $df_x$ is Hurwitz, let $\mathcal{B}$ denote the locally exponentially stable region of attraction of $x^*$. For every $x_0 \in M_e$, the fact that $\lim_{t \to \infty} x(t) = x^*$ implies that there exists a finite $T_{x_0} \geq 0$ such that $x(0) = x_0$ for (19) yields $x(t) \in \mathcal{B}$ for all $t \geq T_{x_0}$. Now, $\mathcal{M}_e$ is compact, which implies that there exists a $\bar{T} \geq \max_{x_0 \in \mathcal{M}_e} T_{x_0}$ such that for all $x(0) \in \mathcal{M}_e$, there holds $x(t) \in \mathcal{B}$ for all $t \geq \bar{T}$. In other words, there exists a time $\bar{T}$ independent of $x(0)$, such that any trajectory of (19) beginning in $\mathcal{M}_e$ enters the region of attraction $\mathcal{B}$ of the locally exponentially stable equilibrium $x^*$. Because $\bar{T}$ is independent of the initial conditions, there exist positive constants $\alpha_1$ and $\alpha_2$ such that

$$||x(t) - x^*|| \leq \alpha_1 e^{-\alpha_2 t} ||x(0) - x^*||$$

for all $x(0) \in \mathcal{M}_e$ and $t \geq 0$. That is, $\lim_{t \to \infty} x(t) = x^*$ exponentially fast for all $x(0) \in \mathcal{M}_e$.

We conclude our analysis of the controlled SIS network model by establishing that decentralized feedback control always pushes the endemic equilibrium closer to the healthy equilibrium (the proof is given in Appendix C).

**Lemma 5:** Consider the system (19), with $G = (V, E, B)$ strongly connected, and $\Xi$, defined in (2). Suppose that $s(-D + B) > 0$, and that for all $i \in V$, $h_i : [0, 1] \to \mathbb{R}_{\geq 0}$ is bounded, smooth, and monotonically nondecreasing, satisfying $h_i(0) = 0$ and $\exists j : x_j > 0 \Rightarrow h_i(x_j) > 0$. Let $x^*$ and $\tilde{x}^*$ denote the unique endemic equilibrium of (4) and (19), respectively. Then, $\tilde{x}^* < x^*$.

It is worth noting that the presence of a single node $j$ with positive control, i.e., $x_j > 0 \Rightarrow h_j(x_j) > 0$, leads to an improvement for every node $i$, i.e., $x_i^* < x_i^*$. This would not be expected if $G$ was not strongly connected.

### C. Illustrative Simulation Example

In this subsection, we provide a simple simulation example of a controlled SIS system in (19) with $n = 2$ nodes. The aim is to illustrate the impact on the SIS network dynamics via the introduction of feedback control, to provide an intuitive explanation and discuss the implications of Theorem 4 and Lemma 5. We therefore choose the parameters and specific control functions $h_i$ arbitrarily; the salient conclusions presented below are unchanged for many other choices of parameters and controllers. We set

$$D = \begin{bmatrix} 0.3 & 0 \\ 0 & 0.8 \end{bmatrix}, \quad B = \begin{bmatrix} 0.2 & 0.5 \\ 0.7 & 0.1 \end{bmatrix}$$

which yields $s(-D + B) = 0.2633$.

When there is no control, i.e., $h_1(x_1) \equiv h_2(x_2) \equiv 0$, the vector-valued function

$$f(x) = (-D + (I_n - X)B)x$$

defines the dynamics of (4) and represents the vector field shown in Fig. 2. Since $s(-D + B) > 0$, the endemic equilibrium $x^* = [0.4413, 0.2973]^	op$ (the red dot) is attractive for all $x(0) \in \Xi \setminus \{0\}$, as per Item 2 of Proposition 1 and Theorem 4.

We then introduce the feedback controllers $h_1(x_1) = 0.5x_1^{0.5}$ and $h_2(x_2) = 0.9x_2$ into the SIS network model, given in (19). The resulting vector field is shown Fig. 3.

---

$^5$As detailed in Appendix A, Proposition 4 is an extension of a well-known result, viz., Lemma 9, when there is a unique equilibrium.
by the vector-valued function
\[ \tilde{f}(x) = (-D - H(x) + (I_n - X) B)x. \] (25)
Although the introduction of the \( h_i \) has modified the vector-valued function to become \( \tilde{f} \), there remains a unique zero in \( \text{Int}(\Xi_n) \). In the context of the SIS model, there is a unique endemic equilibrium \( \bar{x}^e = [0.15, 0.1142]^{\top} \), and consistent with Theorem 4, all trajectories with \( x(0) \in \Xi_n \setminus 0_n \) converge to \( \bar{x}^e \).

Comparing Figs. 2 and 3, one sees that the feedback control has shifted the endemic equilibrium from \( x^* \) to \( \bar{x}^e \), which clearly obeys the inequality \( \bar{x}^e < x^* \) as detailed in Lemma 5.

To summarize, Theorem 4 provides us with conclusions on a broad class of decentralized feedback controllers. Specifically, if the underlying uncontrolled system has a unique endemic equilibrium (that is convergent for all \( x(0) \in \Xi_n \setminus 0_n \)), then no matter how we design the control functions \( h_i(x_i) \), there will always be a unique endemic equilibrium that is convergent for all \( x(0) \in \Xi_n \setminus 0_n \). In the language of Theorem 1, introduction of \( h_i \) modifies the vector-valued function \( f \) in (24) to become \( \tilde{f} \) in (25), but does not change the stability of the Jacobian matrix at any zero in \( M \), preserving the uniqueness property. This demonstrates the challenge of attempting decentralized control where each node only utilizes local state \( x_i \) for information. Nonetheless, Lemma 5 demonstrates that some health benefits are obtained, since there is at equilibrium a smaller fraction of infected individuals at each population.

From Theorem 3, the healthy equilibrium is globally asymptotically stable for the controlled network if and only if the underlying uncontrolled network itself has the property that \( x = 0_n \) is globally asymptotically stable, i.e. \( s(-D + B) \leq 0 \). If \( s(-D + B) > 0 \), one may wish to consider other decentralized or distributed control methods, including controlling the infection rates as functions of \( x \), e.g. \( b_{ij}(x_j(t), x_i(t)) \). If only local information \( x_j(t) \) for population \( i \) is available, one might require nonsmooth or time-varying or adaptive controllers; in this case, the Poincaré–Hopf theorem, and consequently Theorem 1, is not applicable (at least not without significant modifications).

D. Discussions on the Analysis Framework
To conclude this section, we use the result of Theorem 4 to drive our discussion on the strengths and weaknesses of our analysis framework, including especially Theorem 1.

Theorem 1 establishes local exponential stability of the unique equilibrium \( x^* \), and notice that this does not exclude the possibility of limit cycles or chaos. Indeed, in the next section, we consider a different biological system model known to exhibit limit cycles and chaotic behavior and derive a sufficient condition for a unique equilibrium \( x^* \) without requiring global convergence to \( x^* \). However, if one believes that there is global convergence, then proving the uniqueness of \( x^* \) can be a critical step, as it may inform of potential approaches for studying convergence. In the existing work, a sufficient condition is identified using monotone systems theory that guarantees (1) for all initial conditions either converges to \( 0_n \), or converges to a unique equilibrium \( x^* \) in \( \mathbb{R}_{\geq 0}^n \) [35, Th. 11]. However, such a result does not help to establish whether \( x^* \) actually exists. Moreover, [35, Th. 11] cannot be used to obtain Theorem 4, since the required condition is satisfied for the uncontrolled SIS system (4), but is not guaranteed to be satisfied for the controlled SIS system (19).

One advantage of Theorem 1 is that it enables one to analyze modifications to existing models, without significantly changing the analysis technique. In Section IV-B, we modified the standard SIS network model by adding decentralized feedback control, in the process destroying the quadratic character of the differential equation set. Application of Theorem 1 to cover a broad class of controllers involves only minor adjustments between the analysis of the uncontrolled network (see Theorem 2) and the controlled network (see Theorem 4). The same technique as in Theorem 4 can also be used to analyze another variant of the SIS model, known as the SIS network model in a “patchy environment” [43], [44], which aims to capture infection due to individuals traveling between population nodes.

In contrast, the algebraic-based approach of [16]–[18] has the advantage of being able to explicitly compute (albeit in a centralized way) the endemic equilibrium for (4) and examine weakly connected networks [17] or nodes with zero recovery rates, \( d_i = 0 \) [22]. However, such an approach cannot be easily adapted to the patchy environment SIS model or handle broad classes of feedback control as in Section IV-B. The Lyapunov-based approach of [1] can be used to study the patchy environment models [45] and has the advantage of simultaneously establishing the uniqueness of the endemic equilibrium \( x^* \) and global convergence. However, the Lyapunov functions of [1] and [45] cannot be extended to consider the model with decentralized feedback control, as we did in Section IV-B. One requires searching for a new Lyapunov function, which may be difficult to identify and also may not cover a broad class of controllers as we have.

One drawback of Theorem 1 is the need to identify a manifold \( M \), which has specific properties, such as being contractible and with \( f \) pointing inward to \( M \) at every point on the boundary \( \partial M \). This is not always straightforward. Nonetheless, many models in the natural sciences will be well defined for some positively invariant set of the state space, which may be used as a basis to inform the identification of \( M \). Once \( M \) has been identified, it may be reused for modified variants of the system. In Section IV-A, we identify an appropriate \( M \) for the uncontrolled SIS network model given in (4); a near identical \( M \) can be used for the controlled SIS network model given in (19).

Last, and as we will next demonstrate, Theorem 1 can be applied to other classes of models; one can view Theorem 1 as a useful tool in the first step in analyzing general systems given by (1), and not as a stand-alone, all powerful result.

V. LOTKA–VOLTERRA SYSTEMS
We now illustrate the versatility of Theorem 1 (from Section III), by applying it to a different model in the natural sciences. While Section IV considers the SIS networked epidemic model, including with feedback control, this section considers the generalized nonlinear Lotka–Volterra model. We use Theorem 1 to identify conditions for the existence of a
unique nontrivial equilibrium and establish its local stability property. We require some additional linear algebra results. For a matrix $A \in \mathbb{R}^{n \times n}$, whose diagonal entries satisfy $a_{ii} > 0, \forall i = 1, \ldots, n$, consider the following four conditions.

C1) There exists a positive diagonal $D$ such that $AD$ is strictly diagonally dominant, i.e., there holds

$$d_{i}a_{ii} > \sum_{j \neq i}^{n} d_{j}|a_{ij}| \quad \forall i = 1, 2, \ldots, n. \quad (26)$$

C2) There exists a diagonal positive $C$ for which $AC + CA^{T}$ is positive definite.

C3) All the leading principal minors of $A$ are positive.

C4) $A$ is a nonsingular $M$-matrix (see Lemma 2).

Two simple lemmas flow from this.

**Lemma 6** (see [28, Ch. 6]): Consider a matrix $A \in \mathbb{R}^{n \times n}$, with diagonal entries satisfying $a_{ii} > 0, \forall i = 1, \ldots, n$. Then, C1 $\Rightarrow$ C2 $\Rightarrow$ C3. If further $A$ has all off-diagonal elements nonpositive, then C1 $\Rightarrow$ C2 $\Rightarrow$ C3 $\Rightarrow$ C4.

**Lemma 7:** Let $A \in \mathbb{R}^{n \times n}$ be a matrix such that C1 holds, with diagonal entries satisfying $a_{ii} > 0, \forall i = 1, \ldots, n$. Suppose $B \in \mathbb{R}^{n \times n}$ is a matrix related to $A$ by

$$b_{ii} \geq a_{ii} \quad \quad |b_{ij}| \leq |a_{ij}|, \quad i \neq j.$$ 

Then, $B$ satisfies C1 with the same matrix $D$ as used in the defining strict diagonal dominance inequalities for $A$.

The proof is straightforward and follows by observing that each of the inequalities in (26) holds with $a_{ii}$ and $a_{ij}$ replaced by $b_{ii}$ and $b_{ij}$, respectively, in view of the inequalities in the lemma statement.

### A. Generalized Nonlinear Lotka–Volterra Models

The basic Lotka–Volterra models consider a population of $n$ biological species, with the variable $x_{i}$ associated to species $i \in \{1, \ldots, n\}$. Typically, $x_{i} \geq 0$ denotes the population size of species $i$ and has dynamics

$$\dot{x}_{i}(t) = d_{i}x_{i}(t) + \sum_{j=1}^{n} a_{ij}x_{j}(t) \quad x_{i}(t) \quad (27)$$

With $x = [x_1, \ldots, x_n]^T$, the matrix form is given by

$$\dot{\mathbf{x}}(t) = (D + X(t))\mathbf{x}(t) \quad \quad (28)$$

where $D = \text{diag}(d_1, \ldots, d_n)$ and $X = \text{diag}(a_{11}, \ldots, a_{nn})$. For the matrix $A$, there are no a priori restrictions on the signs of the $a_{ij}$, though generally diagonal terms are taken as negative. It is understood that almost exclusively, interest is restricted to systems in (28) with $D$ and $A$ such that $x(0) \in \mathbb{R}_{>0}^{n}$ implies $x(t) \in \mathbb{R}_{>0}^{n}$ for all $t \geq 0$. That is, the positive orthant $\mathbb{R}_{>0}^{n}$ is a positive invariant set of (28).

The literature on Lotka–Volterra systems is vast. We note a small number of key aspects. For an introduction, one can consult [3]. Many behaviors can be exhibited: indeed, [4] establishes that an $n$-dimensional Lotka–Volterra system can be constructed with the property that trajectories converge to an $(n-1)$-dimensional linear subspace, in which the motion can follow that of any $(n-1)$-dimensional system. Since a second-order system can exhibit limit cycles and a third-order system can exhibit limit cycles, strange attractors, or chaos, these behaviors can be found in third or fourth (or higher) order Lotka–Volterra systems. The original prey–predator system associated with the names Lotka and Volterra is second order and can display nonattracting limit cycles, as well as having a saddle point equilibrium and a nonhyperbolic equilibrium (see [46]).

The original prey–predator system assumes that $a_{12}$ and $a_{21}$ have different signs. Many higher dimensional Lotka–Volterra systems have mixed signs for the $a_{ij}$ in fact, due to the applications relevance. Nevertheless, those for which all $a_{ij}$ are positive (cooperative systems) and all are negative (competitive systems) have enjoyed significant attention.

A generalization of the Lotka–Volterra system in (27) is proposed in [23] as

$$\dot{x}_{i}(t) = F_{1}(x_{1}(t), x_{2}(t), \ldots, x_{n}(t))x_{i}(t) \quad (29)$$

for $i = 1, 2, \ldots, n$. $F_{i}$ are assumed to be at least two times continuously differentiable, and (27) is obtained with the identification

$$F_{i}(x_{1}, x_{2}, \ldots, x_{n}) = d_{i} + \sum_{j=1}^{n} a_{ij}x_{j}.$$ 

One can write the vector form of (29) as

$$\dot{\mathbf{x}}(t) = F(x)\mathbf{x} \quad (30)$$

where $F = \text{diag}(F_{1}(x), \ldots, F_{n}(x)) \in \mathbb{R}^{n \times n}$, and we assume that (30) is such that $x(0) \in \mathbb{R}_{>0}^{n}$ implies $x(t) \in \mathbb{R}_{>0}^{n}$ for all $t \geq 0$. It is obvious that (30) has the trivial equilibrium $x = 0_{n}$. We comment now on other equilibria in the positive orthant. A nontrivial equilibrium $\bar{x} \in \mathbb{R}_{>0}^{n}$ is termed feasible. An equilibrium $\bar{x} \in \mathbb{R}_{>0}^{n}$ is termed partially feasible if there exist $i, j \in \{1, \ldots, n\}$ such that $\bar{x}_{i} > 0$ and $\bar{x}_{j} = 0$. We are interested in establishing a condition for the existence and uniqueness of a feasible equilibrium for (30).

If each $F_{i}$ in (29) has the property that it is positive everywhere on the boundary of the positive orthant where $x_{i} = 0$, there can be no stable equilibria on the boundary, and just inside such a boundary, motions will have a component along the inwardly directed normal to the boundary. If $F_{i}$ have the further property that whenever $x \in \mathbb{R}_{>0}^{n}$ is such that $\|x\| > R$ for some constant $R$, there holds $\sum_{i=1}^{n} F_{i}(x_{1}, x_{2}, \ldots, x_{n})x_{i}^{2} < 0$, then the motions of (30) will be pointed inwards into $\mathbb{R}_{>0}^{n} \cap \{x : \|x\| \leq R\}$ when $\|x\| = R$. Note that such an assumption on $F_{i}$ ensures that the population size $x_{i}(t)$ of species $i$ does not tend to infinity for any $t \leq \infty$, ensuring the population dynamics are well defined for all time. By using Proposition 2, it follows that the interior of the set $\mathbb{R}_{>0}^{n} \cap \{x : \|x\| \leq R\}$ is an invariant of the motion. We now use Theorem 1 to derive a sufficient condition for (30) to have a unique feasible equilibrium.

**Theorem 5:** Consider the system (30) with $F_{i} \in C^{2}$ for all $i = 1, \ldots, n$. Suppose that there exist constants $R, \epsilon > 0$ such that $W = \{x : \|x\| \leq R, x_{i} \geq \epsilon \forall i = 1, \ldots, n\}$ is a positive invariant set and $F(x)$ points inward at every $x \in \partial W$. Then, there
exists a feasible equilibrium in \( \text{Int}(\mathcal{W}) \). Suppose further that for any equilibrium point \( \bar{x} \in \mathcal{W} \):

\[
\frac{\partial F_i(\bar{x})}{\partial x_i} \leq a_{ii} < 0
\]

for some constant matrix \( A \), for which \(-A\) satisfies C3. Then, there is a unique feasible equilibrium \( x^* \in \text{Int}(\mathcal{W}) \), and \( x^* \) is locally exponentially stable.

**Proof:** Now, because of the \( C^\infty \) assumption on the \( F_i \), an argument set out in [15, Lemma 4.1], and appealing to Brouwer’s fixed-point theorem establishes that there is at least one equilibrium point in the convex and compact set \( \mathcal{W} \). Notice that all equilibria \( \bar{x} \in \mathcal{W} \) are feasible, satisfying \( \bar{x} > 0_n \). It follows from (30) that \( F_i(\bar{x}_1, \bar{x}_2, \ldots, \bar{x}_n) = 0 \forall i = 1, \ldots, n \).

Let \( J_F(x) \) denote the Jacobian of the vector-valued function \( F = [F_1(x), \ldots, F_n(x)]^\top \) evaluated at \( x \). The Jacobian of the system (30), denoted \( df_x \), to be consistent with the notation in Section III, is computed to be

\[
df_x = XJ_F(x) + F(x)
\]

which at an equilibrium \( \bar{x} \in \mathcal{W} \) is simply

\[
df_{\bar{x}} = \bar{X}J_F(\bar{x}).
\]

First observe that the inequalities in (31) imply that \( a_{ij} \geq 0 \) for \( i \neq j \), and this means that \(-A\) has all off-diagonal entries nonpositive. Lemma 6 establishes that \(-A\) satisfying C3 (as per the theorem hypothesis) is equivalent to \(-A\) being a nonsingular \( M \)-matrix, and this is, in turn, equivalent to the existence of a positive diagonal \( D \) for which \(-AD\) is strictly diagonally dominant. Using Lemma 7 and (31), it is then evident that \(-J_F(\bar{x})D\) is strictly diagonally dominant, and it follows that \(-\bar{X}J_F(\bar{x})D\) is also strictly diagonally dominant. That is, \(-\bar{X}J_F(\bar{x})D\) satisfies C1. Lemma 6 implies that there exists a diagonal positive \( C \) for which

\[
-\left( \bar{X}J_F(\bar{x})D \right)C + CDJ_F(\bar{x})\bar{X}
\]

is positive definite (Condition C2). Since \( DC = CD \) is a positive-definite matrix, this implies that \( df_{\bar{x}} = \bar{X}J_F(\bar{x}) \) has all eigenvalues in the left half plane. Inequality (31) is assumed to hold for all equilibria \( \bar{x} \in \mathcal{W} \), which implies that \( df_{\bar{x}} \) is Hurwitz for all equilibria \( \bar{x} \in \mathcal{W} \). Theorem 1 then establishes the fact that there is, in fact, a unique feasible equilibrium \( x^* \in \text{Int}(\mathcal{W}) \), and \( x^* \) is locally exponentially stable. □

If, in fact, (31) holds for all \( x \in \mathcal{W} \), then one has global convergence: \( \lim_{t \to \infty} x(t) = x^* \) for all \( x(0) \in \mathcal{W} \) exponentially fast. To establish this, first recall that \( F_i(x^*) = 0 \) for each \( i \). Observe that for each \( i \), one has

\[
\dot{x}_i = F_i(x)x_i = \left( \sum_{j=1}^{n} \frac{\partial F_i(\bar{x})}{\partial x_j}(x_j - x_j^*) \right) x_i
\]

with \( \bar{x}_j \) taking some value existing by the mean value theorem between \( x_j \) and \( x_j^* \). Now, set \( y_i = |x_i - x_i^*| \) for each \( i \). It is not hard to verify using (31) and (33) that

\[
\dot{y}_i \leq \epsilon \left( \frac{\partial F_i(\bar{x})}{\partial x_i} y_i + \sum_{j \neq i} \frac{\partial F_i(\bar{x})}{\partial x_j} y_j \right)
\]

\[
\leq \epsilon \left( a_{ii} y_i + \sum_{j \neq i} a_{ij} y_j \right)
\]

(34)

where \( \epsilon > 0 \) is defined in Theorem 5. Let \( z = [z_1, \ldots, z_n]^\top \) and \( y = [y_1, \ldots, y_n]^\top \). Consider the system

\[
\dot{z}(t) = \epsilon Az(t), \quad z(0) = y(0).
\]

From (34), we obtain that \( \dot{y}_i(t) - \epsilon A y_i(t) \leq \dot{z}(t) - \epsilon A z(t) \) for all \( t \). The properties of \( A \) detailed in Theorem 5 allows the main theorem of [47] to be applied, which establishes that \( y(t) \leq z(t) \) for all \( t \). Because \( A \) is Hurwitz, it follows that \( \lim_{t \to \infty} z(t) = 0_n \), and therefore, \( y_i(t) = |x_i(t) - x_i^*| \) converges to zero, as required.

**Remark 4:** It was first established in [23] that if (31) holds for all \( x \in \mathcal{W} \), then \( \lim_{t \to \infty} x(t) = x^* \) for all \( x(0) \in \mathbb{R}^n_{>0} \cap \mathcal{W} \), where \( x^* \) is a feasible equilibrium. The uniqueness of \( x^* \) was never explicitly proved in [23], but rather implicitly by constructing a complex Lyapunov-like function, which simultaneously yielded uniqueness and convergence. Theorem 5 relaxes the result of [23] in the sense that the inequalities in (31) are only required to hold when \( F_i(x) = 0 \) for all \( i \) and \( x \in \mathcal{W} \), and we explicitly prove the uniqueness property. Moreover, it is conceivable that some forms of (30) have a unique feasible equilibrium while still exhibiting chaotic behavior, limit cycles, and other dynamical behavior associated with Lotka–Volterra systems. We then, separately, recover the global convergence result of [23] by a simple argument without requiring Lyapunov-like functions.

**VI. DISCRETE-TIME COUNTERPART**

For many processes in the natural and social sciences, both continuous- and discrete-time models exist. For example, various works have studied discrete-time epidemic models [48], [49] and Lotka–Volterra models [50]. As a consequence, it is natural for systems and control engineers to consider the same set of questions for both continuous- and discrete-time models, such as the uniqueness of the equilibrium. (Whether continuous- or discrete-time models are more appropriate is beyond the scope of this article, and often depends on the problem context and other factors). In this section, we present a discrete-time counterpart to Theorem 1 for the nonlinear system

\[
x(k + 1) = G(x(k))
\]

(35)

and show an example application on the DeGroot–Friedkin model of a social network [26], [51]. This counterpart result first appeared in [24, Th. 3]. Note that a point \( \bar{x} \) satisfying \( G(\bar{x}) = \bar{x} \) is said to be a fixed point of the nonlinear mapping \( G \), and \( \bar{x} \) is an equilibrium of (35).

**Theorem 6:** Consider a smooth map \( G : X \to X \), where \( X \) is a compact and contractible manifold of finite dimension.
Suppose that for all fixed points \( \bar{x} \in X \) of \( G \), the eigenvalues of \( dG_{\bar{x}} \) have magnitude less than 1. Then, \( G \) has a unique fixed point \( x^* \in X \), and in a local neighborhood about \( x^* \), (35) converges to \( x^* \) exponentially fast.

Rather than presenting the proof of the theorem, which can be found in [24] and requires some additional knowledge and results on the Lefschetz–Hopf theorem [25], [52], we instead provide some comments relating Theorems 1 and 6. First, we note that the existence of a homotopy between \( G \) and the identity map is central to the proof of Theorem 6, as detailed in [24, Th. 3]. Consequently, [24] required \( X \) to be a compact, oriented, and convex manifold or a convex triangular space of finite dimension so that a specific homotopy between \( G \) and the identity map could be constructed. However, [52, Th. 5.19] identifies that for any compact and contractible \( X \), there exists a homotopy between any map \( G : X \to X \) and the identity map. Thus, we can relax the hypothesis in Theorem 6 from [24, Th. 3] to allow for \( X \) to be compact and contractible.

\textit{Mutatis mutandis,} Theorems 1 and 6 are, therefore, equivalent. The requirement in Theorem 1 that \( df_{\bar{x}} \) is Hurwitz for all zeroes \( \bar{x} \) of \( f(\cdot) \) in (1) is equivalent to the requirement in Theorem 6 that for all fixed points \( \bar{x} \) of \( G \) in (35), \( dG_{\bar{x}} \) has eigenvalues all with magnitude less than 1.

### A. Application to the DeGroot–Friedkin Model

In [24], Theorem 6 is applied to the DeGroot–Friedkin model [26], which describes the evolution of individual self-confidence, \( x_i(k) \), as a social network of \( n \geq 3 \) individuals discusses a sequence of issues, \( k = 0, 1, 2, \ldots \). We provide a summary of the application here. The map \( G \) in question is

\[
G(x(k)) = \frac{1}{\sum_{i=1}^{n} \gamma_i} \begin{bmatrix}
\gamma_1 & 1 - x_1(k) \\
\vdots & \vdots \\
\gamma_n & 1 - x_n(k)
\end{bmatrix} \tag{36}
\]

where \( \gamma_i \in (0, 0.5) \), and \( \sum_{i=1}^{n} \gamma_i = 1 \). The compact, convex, and oriented manifold of interest is

\[
\Delta_n = \left\{ x_i : \sum_{i=1}^{n} x_i = 1, 0 < \delta \leq x_i \leq 1 - \delta \right\}
\]

where \( \delta > 0 \) is arbitrarily small. One can regard \( \Delta_n \) as a compact subset in the interior of the \((n - 1)\)-dimensional unit simplex, and it can be shown that \( G : \Delta_n \to \Delta_n \) for sufficiently small \( \delta \) [26], [51].

Now, \( G \) in (36) is given with coordinates in \( \mathbb{R}^n \), whereas \( \Delta_n \) is a manifold of dimension \( n - 1 \). Thus, an appropriate \( \mathbb{R}^{n-1} \) coordinate basis is proposed in [24], with an associated map \( G \) on the manifold \( \Delta_n \). Then, Anderson and Ye [24] establish that the eigenvalues of \( dG_{\bar{x}} \) at every fixed point \( \bar{x} \in \Delta_n \) are all of magnitude less than 1. This is done by showing that the eigenvalues of \( dG_{\bar{x}} \) are a subset of the eigenvalues of a Laplacian matrix \( \mathcal{L} \) associated with a strongly connected graph. It is well known that such a Laplacian has a single zero eigenvalue, and all other eigenvalues have positive real part. In fact, Anderson and Ye [24] show that the particular \( \mathcal{L} \) has all real eigenvalues, and its trace is 1. Since \( n \geq 3 \), it immediately follows that all eigenvalues of \( \mathcal{L} \), and by implication, all eigenvalues of \( dG_{\bar{x}} \) are less than 1 in magnitude.

One can then apply Theorem 6 to establish that \( \tilde{G} \) has a unique fixed point \( \bar{x}^* \) in \( \Delta_n \) (and consequently the \( G \) in (36)), and \( \bar{x}^* \) is locally exponentially stable for the system (35). We refer the reader to [24, Th. 4] for the details. We conclude by remarking that the first proof of the uniqueness of \( \bar{x}^* \) in \( \Delta_n \) for \( G \) in (36) required extensive and complex algebraic manipulations (see [26, Appendix F]). In comparison, the calculations required to establish the uniqueness of \( \bar{x}^* \) in \( \Delta_n \) for \( G \) in (36) using Theorem 6 are greatly simplified and may continue to hold for generalizations of (36), as studied in [53].

### VII. Conclusion

We have used the Poincaré–Hopf theorem to prove that a nonlinear dynamical system has a unique equilibrium (that is actually locally exponentially stable) if inside a compact and contractible manifold, its Jacobian at every possible equilibrium is Hurwitz. We illustrated the method by applying it to analyze the established deterministic SIS networked model, and an extension that introduces decentralized controllers, rendering the system no longer quadratic. We proved a general impossibility result: if the uncontrolled system has a unique endemic equilibrium, then the controlled system also has a unique endemic equilibrium, which is locally exponentially stable. That is, the controllers can never globally drive the networked system to the healthy equilibrium. A stronger almost global convergence result was obtained by extending a result from monotone dynamical systems theory, with the extension relying on the fact that the endemic equilibrium was unique. A generalized nonlinear Lotka–Volterra model was also analyzed. Last, a counterpart sufficient condition was presented for a nonlinear discrete-time system to have a unique equilibrium in a compact and contractible manifold. For future work, we hope expand the analysis framework presented in this article and identify further applications, especially focusing on various models within the natural sciences. This includes the introduction of control to other existing epidemic models.

### APPENDIX

#### A. Monotone Systems

A simple introduction to monotone systems is provided, sufficient for the purposes of this article. A general convergence result is then developed, to be used in Section IV-B. For details, the reader is referred to [20] and [21]. We impose slightly more restrictive conditions than in [20] and [21] for the purposes of maintaining the clarity and simplicity of this section.

To begin, let \( m = [m_1, \ldots, m_n]^\top \in \mathbb{R}^n \), with \( m_i \in \{0, 1\} \) for \( i = 1, \ldots, n \). Then, an orthant of \( \mathbb{R}^n \) can be defined as

\[
K_m = \{ x \in \mathbb{R}^n : (-1)^{m_i} x_i \geq 0, \forall i \in \{1, \ldots, n\} \}. \tag{37}
\]

For a given orthant \( K_m \in \mathbb{R}^n \), we write \( x \leq_{K_m} y \) and \( x <_{K_m} y \) if \( y - x \in K_m \) and \( y - x \in \text{Int}(K_m) \), respectively.

---

6As defined in Section III-A, \( dG_{\bar{x}} \) is the Jacobian of \( G \) in the local coordinates of \( x \in X \).
We consider the system (1) on a convex open set $U \subseteq \mathbb{R}^n$ and assume that $f$ is sufficiently smooth such that $df_x$ exists for all $x \in U$, and the solution $x(t)$ is unique for every initial condition in $U$. We use $\phi_t(x_0)$ to denote the solution $x(t)$ of (1) with $x(0) = x_0$. If whenever $x_0, y_0 \in U$, satisfying $x_0 \leq K_m, y_0$, implies $\phi_t(x_0) \leq K_m, \phi_t(y_0)$ for all $t \geq 0$ for which both $\phi_t(x_0)$ and $\phi_t(y_0)$ are defined, then the system (1) is said to be a type $K_m$ monotone system and the solution operator $\phi_t(x_0)$ of (1) is said to preserve the partial ordering $\leq K_m$ for $t \geq 0$. The following is a necessary and sufficient condition for (1) to be type $K_m$ monotone and focuses on the Jacobian $df_x$ of $f(\cdot)$ in (1).

**Lemma 8 (Kamke–Miller condition [20, Lemma 2.1]):** Suppose that $f$ is of class $C^1$ in $U$, where $U$ is open and convex in $\mathbb{R}^n$. Then, $\phi_t(x_0)$ of (1) preserves the partial ordering $\leq K_m$ for $t \geq 0$ if and only if $P_m df_x P_m$ has all off-diagonal entries nonnegative for every $x \in U$, where $P_m = \text{diag}((-1)^{m_1}, \ldots, (-1)^{m_n})$.

Many results exist establishing convergence of type $K_m$ monotone systems, with various additional assumptions imposed. Here, we state one which has some stricter assumptions and then extend it for use in our analysis in Section IV-B. Let $E$ denote the set of equilibria of (1), and for an equilibrium $e \in E$, the basin of attraction of $e$ is denoted by $B(e)$. We say (1) is an irreducible type $K_m$ monotone system if $df_x$ is irreducible for all $x \in U$.

**Lemma 9 (see [20, Th. 2.6]):** Let $\mathcal{M}$ be an open, bounded, and positively invariant set for an irreducible type $K_m$ monotone system (1). Suppose the closure of $\mathcal{M}$, denoted by $\overline{\mathcal{M}}$, contains a finite number of equilibria. Then

$$\bigcup_{e \in E \cap \overline{\mathcal{M}}} \text{Int}(B(e)) \cap \overline{\mathcal{M}}$$

is open and dense in $\overline{\mathcal{M}}$.

A set $S \subseteq A$ is dense in $A$ if every point $x \in A$ is either in $S$ or in the closure of $S$. Thus, Lemma 9 states that for an irreducible type $K_m$ monotone system (1), the system converges to an equilibrium $e \in E \cap \overline{\mathcal{M}}$ for almost all initial conditions in $\mathcal{M}$. There are at most a finite number of nonattractive limit cycles. A stronger result is available, appearing in [54, Th. D], and presented below with a different simpler proof. The result will be used in Section IV.

**Proposition 4 (cf. [54, Th. D]):** Let $\mathcal{M}$ be an open, bounded, convex, and positively invariant set for an irreducible type $K_m$ monotone system (1). Suppose there is a unique equilibrium $e^* \in \mathcal{M}$ and no equilibrium in $\overline{\mathcal{M}} \setminus \mathcal{M}$. Then, convergence to $e^*$ occurs for every initial condition in $\mathcal{M}$.

**Proof:** First, we remark that an irreducible type $K_m$ monotone system (1) enjoys a stronger monotonicity property; for any $x_1, x_2 \in \mathcal{M}$, one has that $x_1 < K_m x_2 \Rightarrow \phi_t(x_1) < K_m \phi_t(x_2)$ for all $t > 0$ [21].

In light of Lemma 9, the proposition is proved if we establish that there does not exist a limit cycle. We argue by contradiction. Let $a$ be a point on such a limit cycle of (1). Pick two points $a \in \mathcal{M}$ and $\bar{a} \in \mathcal{M}$ satisfying $a < K_m, a < K_m, \bar{a}$, and observe that there exist two sufficiently small balls $B_1$ and $B_2$ surrounding $a$ and $\bar{a}$, respectively, which neither intersect the boundary of $\mathcal{M}$ nor contain $a$, and every point $x \in B_1$ and $y \in B_2$ obey $x < K_m a < K_m y$. Since almost every point in $B_1$ is not in a nonattractive limit cycle, there exists an $x_1 \in B_1$ such that $\lim_{t \to \infty} \phi_t(x_1) = e^*$. Similarly, there exists a $y_0 \in B_2$ such that $\lim_{t \to \infty} \phi_t(y_0) = e^*$. Because $x_1 < K_m a < K_m y_0$, it follows that $\phi_t(x_1) < K_m, \phi_t(a) < K_m, \phi_t(y_0)$. Recalling that $\lim_{t \to \infty} \phi_t(x_1) = e^*$ and $\lim_{t \to \infty} \phi_t(y_0) = e^*$ yields $\lim_{t \to \infty} \phi_t(a) = e^*$. However, this contradicts the assumption that $a$ is a point on a nonattractive limit cycle. □

**B Proof of Lemma 4**

To begin, we prove the first part of the lemma statement. Fixing $i \in \{1, \ldots, n\}$, we need to show that $-e_i \dot{x} = -\dot{x}_i < 0$ for $x \in P_i$. Now, $x$ satisfies $x_i = e_i y_i$, and for $j \neq i$, we have $x_j = e_j y_j + z_j$ for some $z_j \geq 0$. From (3), we find

$$\dot{x}_i = e_i y_i \left(-d_i y_i + \sum_{j=1}^{n} b_{ij} y_j \right) - e^2 y_i \sum_{j=1}^{n} b_{ij} y_j + (1 - e_j y_i) \sum_{j=1}^{n} b_{ij} z_j. \quad (39)$$

The identity $-(D + B)y = \phi y$ implies $\phi y_i = -d_i y_i + \sum_{j=1}^{n} b_{ij} y_j$, and substituting this into the above and rearranging yields

$$\dot{x}_i = e_i y_i \left(\phi - e \sum_{j=1}^{n} b_{ij} y_j \right) + (1 - e_i y_i) \sum_{j=1}^{n} b_{ij} z_j. \quad (40)$$

Since $\phi > 0$ is constant and $y_k \leq 1$, for all $k$, there exists a sufficiently small $\epsilon_i > 0$ such that for all $\epsilon \leq \epsilon_i$, the first and second summand on the right of (40) are positive and nonnegative, respectively. It follows from (40) that $-e_i \dot{x} < 0$ for all $x \in P_i$. Repeating the analysis for $i = 1, \ldots, n$, it is clear that (15a) holds for all $i = 1, \ldots, n$, for any positive $\epsilon \leq \min_i \epsilon_i$.

Next, fix $i \in \{1, \ldots, n\}$, and consider a point $x \in Q_i$. Now, $e_i \dot{x} = \dot{x}_i$, and (3) yields $\dot{x}_i = -d_i < 0$, and this holds for all $i = 1, \ldots, n$, and thus, (15b) holds. It follows from Proposition 2 that for $0 < \epsilon \leq \min_i \epsilon_i$, $\mathcal{M}_i$ is a positive invariant set of (4). Equation (15) shows that $\partial T_x$ is not an invariant set of (4), which implies that $\text{Int}(\mathcal{M}_i)$ is also a positive invariant set of (4).

To prove the second part of the lemma, consider a point $x(t) \in \partial \mathcal{N} \setminus \mathcal{O}_n$, at some time $t \geq 0$. If $x_i(t) = 1$ for some $i \in \{1, \ldots, n\}$, then (3) yields $\dot{x}_i = -d_i < 0$. Thus, if $x(t) \in \mathcal{O}_n$, then obviously $x(t + \kappa \epsilon) \in \mathcal{M}_{\epsilon_1, \kappa}$ for some sufficiently small positive $\epsilon_1$ and $\epsilon_1 x$.

Let us suppose then that $x(t) \in \partial \mathcal{N} \setminus \mathcal{O}_n$ has at least one zero entry. Define the set $U_i = \{ i : x_i(t) = 0, i \in \{1, \ldots, n\} \}$. The lemma hypothesizes that $G$ is strongly connected, which implies that there exists a $k \in U_i$ such that $x_j(t) > 0$ for some $j \in \mathcal{N}_k$. Equation (3) yields $\dot{x}_k = \sum_{j \in \mathcal{N}_k} b_{kj} x_j(t) \geq b_{kj} x_j(t) > 0$. This analysis can be repeated to show that there exists a finite $\kappa_i$ such that $U_i + \kappa_i$ is empty. It follows that $x(t + \kappa_i) \in \mathcal{M}_{\epsilon_2, \kappa}$, for some sufficiently small $\epsilon_2, \kappa$.

Since $\partial \mathcal{N} \setminus \mathcal{O}_n$ is bounded, there exists a finite $\kappa$ and sufficiently small $\epsilon \in [0, \min_i \{ \epsilon_1, \epsilon_2, \kappa \}]$ such that $x(t) \in \mathcal{M}_i$ for all $x(0) \in \partial \mathcal{N} \setminus \mathcal{O}_n$. Since $\epsilon$ can be taken to be arbitrarily small, it is also clear that any nonzero equilibrium $x$ must satisfy $x \in \text{Int}(\mathcal{N})$. □
C Proof of Lemma 5

Let $\bar{x}' \in \text{Int}(\Xi_n)$ denote the endemic equilibrium of (19), and $ar{H} = \text{diag}(h_1(\bar{x}_1), \ldots, h_n(\bar{x}_n))$. Note the assumption that there exists a $j$ such that $x_j > 0 \Rightarrow h_j(x_j) > 0$ implies $\bar{H}$ is not only a nonnegative diagonal matrix, but also has at least one positive entry. Observe that (19) and

$$
\dot{x} = (-D - \bar{H} + (I_n - X)B)x
$$

have the same positive equilibrium $\bar{x}'$. By arguments introduced previously, we know that $\bar{x}'$ is the only positive equilibrium for (41). Hence $s(-D - \bar{H} + B) > 0$ by Proposition 1. Let $c$ be a sufficiently large constant such that $P(\alpha) = cl_n - D - \bar{H} + B$ is nonnegative for all $\alpha \in [0, 1]$ (note that $\alpha(\bar{H})$ is irreducible). The Perron–Frobenius theorem [28] yields $s(P(\alpha)) = c + s(-D - \bar{H} + B)$. For $\alpha_1 > \alpha_2$, one concludes that $P(\alpha_2)$ is equal to $P(\alpha_1)$ plus some nonnegative diagonal entries (of which at least one is positive), and [28, Corollary 2.1.5] yields that $s(P(\alpha_1)) < s(P(\alpha_2))$. This implies that $s(-D - \bar{H} + B) < s(-D - \bar{H} + B)$. It follows that $s(-D - \bar{H} + B) > 0$ for all $\alpha \in [0, 1]$. Hence, the system

$$
\dot{x} = (-D - \bar{H} + (I_n - X)B)x
$$

has for all $\alpha \in [0, 1]$ a unique equilibrium in $\text{Int}(\Xi_n)$, i.e., $\bar{x}_\alpha$. Notice that $\bar{x}_0 = x'$ [the endemic equilibrium of the uncontrollable system (4)] and $\bar{x}_1 = \bar{x}'$.

Since $\bar{X}_\alpha = \text{diag}((\bar{x}_\alpha)_1, \ldots, (\bar{x}_\alpha)_n)$ is diagonal, there holds $\bar{X}_\alpha = \text{diag}(\bar{X}_\alpha, \ldots, \bar{X}_\alpha)$, where $\bar{B}_\alpha = \frac{\partial}{\partial \bar{x}}(\bar{X}_\alpha)$. Then, differentiating

$$
(-D - \alpha \bar{H} + (I_n - \bar{X}_\alpha)B)\bar{x}_\alpha = 0
$$

with respect to $\alpha$ yields after some rearranging

$$
\frac{d\bar{x}_\alpha}{d\alpha} = -K^{-1}_{\alpha}\bar{H}\bar{x}_\alpha < 0.
$$

Using arguments similar to those laid out in the proof of Theorem 2 (see (16) and below), it can be shown that $K^{-1}_\alpha$ is an irreducible nonsingular $M$-matrix. [28, Th. 2.7] yields that $K^{-1}_\alpha > 0_{n \times n}$. Next, one can verify that $\bar{H} \bar{x}_\alpha > 0_{n \times n}$ has at least one positive entry since $\bar{H}$ has at least one positive entry and $\bar{x}_\alpha > 0_n$. This means that

$$
\frac{d\bar{x}_\alpha}{d\alpha} = -K^{-1}_{\alpha}\bar{H}\bar{x}_\alpha < 0_n.
$$

Integration yields $\bar{x}_0 = x' > \bar{x}' = \bar{x}_1$, as claimed. ■
