Chapter 4

Gray matter volume and white matter lesions in chronic kidney disease: exploring the association with depressive symptoms

Submitted
Abstract

Objective: Chronic kidney disease (CKD) is associated with structural brain damage and with a high prevalence of depression. We therefore investigated structural brain alterations in both gray and white matter in CKD patients, focusing on depression-related (frontal-subcortical) regions.

Methods: This cross-sectional MRI study in 24 CKD patients and 24 age- and sex-matched controls first tested whether CKD was associated with regionally lower gray matter (GM) volumes and more severe white matter lesions (WMLs). In exploratory sub-analyses it was examined whether differences were more pronounced in CKD patients with depressive symptoms.

Results: CKD patients showed lower global GM volume (p=0.04) and more severe WMLs (p=0.04) compared to controls. In addition, we found substantial clusters of lower GM in the bilateral orbitofrontal-cortex for CKD patients, which were however non-significant after proper multiple-comparison-correction. In exploratory analyses for depressed CKD patients, reduced GM-clusters were mainly detected within the frontal lobe. WML severity was unrelated to depression.

Conclusions: CKD was characterized by differences in brain structure. Although subthreshold, lower GM volumes were observed in depression-related brain areas, and were more pronounced for depressed patients. There is a need for replication in larger and longitudinal studies, as our data suggests WMLs and regional GM reductions may render CKD patients more susceptible for depression.
Introduction

Depression is common in patients with chronic kidney disease (CKD). More than a quarter of patients with CKD have elevated depressive symptoms, which is as much as 40% in the most advanced stage of CKD (stage 5). CKD is associated with a high burden of somatic symptoms, disability, and reduced quality of life, predisposing patients to depression.

CKD is also an established risk factor for cerebrovascular disease and subclinical brain changes visualized on MRI, such as white matter lesions (WMLs), reduced white matter integrity, gray matter (GM) atrophy, and hypoperfusion. These abnormalities can be caused by toxic processes and ischemia resulting from a range of underlying processes associated with CKD, such as chronic hypertension, uremia, inflammation, and vascular calcification. Furthermore, hemodialysis (HD) treatment can alter tissue hydration and/or perfusion, which could have additional damaging effects on the brain. Brain alterations associated with CKD may be partly responsible for the high prevalence of depression in patients with CKD.

The vascular depression hypothesis proposes that disruption of frontal-subcortical networks, due to cerebrovascular disease, may lead to depressive symptoms. A late age at onset of depression, the presence of cardiovascular risk factors, and cerebrovascular abnormalities are proposed characteristics of this vascular depression subtype. Some recent meta-analyses including longitudinal and cross-sectional studies in the elderly and in patients with a recent stroke showed that the presence of WMLs was associated with depressive symptoms. In addition, reduced gray matter volumes within the frontal and limbic areas are suggested to play a role in the pathophysiology of depression later in life.

Although both depression and structural brain alterations are common in patients with CKD, very few studies have evaluated whether brain changes in patients with CKD are related to depressive symptoms. Nevertheless, some studies that focused on perfusion in patients with CKD stage 4 and 5 (no dialysis), observed perfusion changes in depression-related brain areas (e.g. the orbitofrontal cortex (OFC)), which were associated with depressive symptoms. To our knowledge, no studies so far focused on the relation between brain structure and depression in the context of CKD. Volumetric neuroimaging studies in CKD patients most consistently reported lower GM volumes in structures within the frontal and temporal lobes, such as in the hippocampus, OFC, and the cingulate cortex. Interestingly, these regions have also been found to be reduced in depressed patients. Abnormalities in these regions may therefore play a role in the association between CKD and depression. Of note, CKD has been associated with diffusely reduced GM volumes, including regions that have not specifically been associated with depression as well. As much as 30-70%
of CKD patients are reported to have WMLs. Some studies suggested that lesion severity (number and size) and lesion localization (frontal-subcortical) are of importance in the association between WMLs and depression in late life. To date, none of the existing studies that reported on the presence and severity of WMLs in CKD patients examined the localization of WMLs.

The aim of the present study was to compare GM volumes and the presence and severity of WMLs in patients with CKD to persons without CKD. We specifically examined whether depression related areas (i.e. frontal-subcortical) were affected. We hypothesize that differences will be more pronounced in patients with depressive symptoms; this was examined in exploratory sub-analyses.

Methods

Participants
MRI data of 24 patients with CKD stages 4 and 5 (mean age 59 years; 21% female), and 24 age- and sex-matched control participants (mean age 57 years; 29% female) were derived from the Depression In the Picture (DIP) study. CKD patients were recruited at the University Medical Center Groningen, Martini Hospital Groningen and Dialysis Center Groningen. Healthy control participants were recruited by means of advertisements at public places and in local newspapers.

Participants of the DIP study had to be older than 18 years. CKD patients had to be in stage 4 or 5 (GFR<30 mL/min/1.73 m²); either pre-dialysis or receiving hemodialysis or peritoneal dialysis (stage 5D). General exclusion criteria were MRI incompatibility, cerebrovascular accidents (CVA), and past or current psychiatric diagnoses other than depressive and anxiety disorders, as these potentially confound results. Specific exclusion criteria for the control group were: a diagnosis of CKD or cardiovascular disease (myocardial infarction, heart failure, CVA, serious stenosis of a major vessel); BDI score ≥10; past or current diagnosis of depressive or anxiety disorder. Furthermore, depressed CKD patients with concrete suicidal plans and currently non-depressed CKD patients with a history of depressive or anxiety disorders were excluded. The study protocol was approved by the local Medical Ethics Committee and all participants gave written informed consent before entering the study.

Measurements
All participants were screened for depressive symptoms using the Beck depression inventory-II (BDI-II). When CKD patients had at least mild symptoms of depression (BDI>13) at screening, they were considered to have elevated depressive symptoms (N=10). The reason for setting different BDI thresholds for CKD and healthy controls, is that CKD patients generally have
higher BDI scores due to somatic symptoms. Excluding patients with a BDI≥10 may therefore result in a selection bias towards relatively healthy patients in the non-depressed group. In addition, psychiatric diagnoses were established using the semi-structured psychiatric interview Mini-Schedules for Clinical Assessment in Neuropsychiatry (Mini-SCAN) according to the Diagnostic and Statistical Manual of mental disorders, fourth edition (DSM-IV) criteria, administered by trained interviewers. Demographic variables and the presence of hypertension and diabetes were assessed by a self-report inventory. For CKD patients, presence of hypertension and diabetes, and laboratory values were also obtained from medical records.

**Data acquisition**
Participants underwent a MRI scan in a 3-Tesla MRI scanner, with a SENSE 32-channel head coil (Philips Intera, Best, NL). A three-dimensional gradient-echo T1-weighted sequence was used to acquire anatomical images (170 slices; TR=9 ms; TE=3.6 ms; matrix=256x231; voxel size=1x1x1 mm; scan duration=4:11 min). In addition, T2-weighted FLAIR scans were used (180 slices; TR=8000 ms; TE=355 ms; matrix=256x255; voxel size=1x1x1 mm; scan duration=4:56 min).

**Data preprocessing Voxel Based Morphometry (VBM) analyses**
Statistical Parametric Mapping software (SPM12), implemented in Matlab 7.8.0, was used to preprocess and analyze the MRI data. First, the images were manually reoriented to the anterior commissure. Then, the standard segmentation option in SPM 12, with the ‘light clean-up’ setting was used to segment the images into GM, white matter (WM), cerebrospinal fluid, skull, and soft tissue outside the brain. Diffeomorphic Anatomical Registration Trough Exponentiated Lie algebra (DARTEL) was used for normalization and modulation of the images. All individual deformation fields were registered to a DARTEL template, created based on the deformation fields produced during the segmentation procedure. After this, the obtained deformed images were used to generate smoothed, spatially normalized, and Jacobian scaled gray and white images in MNI space. To increase the signal to noise ratio, the GM and WM images were smoothed using an 8 mm full-width-half-maximum Gaussian kernel. Voxels were resampled into 1.5x1.5x1.5 mm.

**White matter lesions rating scale**
Periventricular and subcortical WMLs were counted if visible as hyperintense on T2-weighted images, and isointense on T1-weighted images. We used the same scoring method as de Groot et al. used previously. When the WML was adjacent to the lateral ventricle it was considered as periventricular, otherwise as subcortical. Periventricular WMLs (pvWML) were scored for three separate
regions: adjacent to the frontal horns (frontal caps); lateral walls (bands); and occipital horns (occipital caps). The severity for each region was determined based on a scale ranging from 0 to 3 (0=none; 1=pencil thin; 2=moderate; 3=large confluent), with a total periventricular score ranging from 0-9. The number of subcortical WMLs (scWML) was rated for the frontal, temporal, parietal, and occipital lobe, and the insula and cerebellum. Distinction between lobes was according to anatomical landmarks, using http://headneckbrainspine.com. The size of the scWMLs were based on their largest diameter and were counted for four categories: small (<3mm), medium (3-10mm), large (>10mm), and confluent. A total scWML volume (in ml) was approximated by considering scWMLs spherical with a fixed diameter of 2 (small), 6 (medium), or 12mm (large) and adding these volumes. The WMLs were scored by a neuro-radiologist (HL). A consensus reading took place by experienced neuro-radiologist (JCG); no discrepancies were found.

**Statistical analyses**

With SPSS 20.0, demographic and clinical data were analyzed, using chi-square tests and ANOVA. For the gray matter volume analyses, Voxel Based Morphometry (VBM) analyses were masked using a study specific explicit mask to optimize sensitivity and to exclusively select true positive GM voxels for analysis, created with the Masking toolbox of Ridgeway et al. \(^{34}\) We compared total GM volumes between participants with CKD and controls, and subsequently between depressed and non-depressed CKD patients, using ANOVA with a significance level of p<.05. We calculated the relative difference of total GM volume between CKD and controls by considering the total GM volume of controls 100%.

Next, two 2x1 ANOVA analyses were performed in SPM12 to compare GM volumes between 1) CKD patients and age- and sex-matched controls, and 2) in a subsequent exploratory analysis, depressed (BDI>13) and non-depressed patients with CKD (age- and sex-matched). For the whole sample, we first tested for effects occurring in a-priori regions of interest that were chosen based on analogue regions found in previous meta-analyses on volumetric differences in (late-life) depression, \(^{18}\) and in neuroimaging of CKD. \(^{5,12,20,21,35}\) These ROIs included the anterior cingulate cortex (ACC), the orbitofrontal cortex (OFC), and the hippocampus. A composite mask was created using the WFU pickatlas (http://fmri.wfubmc.edu), based on the automated anatomical labeling (AAL) system. All analyses were performed with a one-sided t-test, as we expected to find lower GM volumes for CKD patients. \(^{20,36}\) In addition a whole-brain analysis was performed for the whole sample and for depressed versus non-depressed CKD patients (exploratory analyses). Results of the CKD vs. HC comparison were considered significant after family-wise-error (FWE) cluster-correction (p<.05), with the initial voxel threshold at p<.005 and a spatial cluster extent threshold of...
For effects occurring in our a priori specified ROIs, the area for multiple comparisons control was restricted to the spatial extent of the composite mask. The exploratory analysis was undertaken at the uncorrected threshold of p<.005 and k>50, as this was an underpowered and exploratory analysis. Non-stationarity correction was applied to correct for non-uniformity in image smoothness (http://fmri.wfubmc.edu/cms/software#NS) in all VBM analyses. Furthermore, analyses were corrected for total gray and white matter volume (i.e. Total Brain Volume (TBV)), by using the global values to proportionally scale the original voxel values.

For all WML analyses, we used SPSS. First, we compared the pvWML total scores between CKD patients and controls, using ANOVA. In addition, we compared the presence of scWMLs between CKD patients and controls, using Chi-square. As the presence of only one or two scWMLs is easily confused with blood vessels on a T2-weighted scan, scWMLs were considered present if the total count was at least 3 small scWMLs. Furthermore, we analyzed whether the total lesion load differed between CKD patients and controls using the non-parametric Mann-Whitney U test, as lesion load was not normally distributed. Because localization of WMLs in the frontal lobe may be specifically associated with depressive symptoms, we additionally tested whether CKD was associated with a higher (periventricular and subcortical) lesion load in the frontal lobe compared to controls. All analyses were repeated for depressed versus non-depressed CKD patients, in order to explore whether alterations were more pronounced for depressed patients. All analyses were performed using a threshold of p<.05.

Results

Baseline characteristics
The total sample consisted of 48 participants (mean age: 58; SD:13): 24 CKD patients and 24 age- and sex-matched controls. Causes of CKD were diverse: hypertension (N=2), diabetes (N=4), vascular disease (N=2), polycystic kidney disease (N=4), tubulo-interstitial nephritis (N=2), other or unknown (N=10). Eleven CKD patients received hemodialysis treatment (mean vintage: 23 months) and 1 patient peritoneal dialysis (vintage: 2 months) (for details of hemodialysis settings see Supplementary table 1). Mean creatinine was 814 µmol/l for patients with stage 5D and 391 µmol/l for patients with CKD stage 4 and 5. Mean estimated Glomerular Filtration Rate (eGFR) was 16 mL/min/1.73m² for patients with CKD stage 4 and 5. Patients with CKD had a significantly lower education level, were more often past or current smokers, and had more often diabetes and hypertension compared with control participants (Table 1). Ten CKD patients with current elevated depressive symptoms were included, of which 7 met the DSM-IV criteria for depression and 2 used anti-depressive medication.

SD = standard deviation; CKD = chronic kidney disease; DEP- = no elevated depressive symptoms; DEP+ = elevated depressive symptoms; BDI = Beck Depression Inventory; eGFR = estimated Glomular Filtration Rate

*Two participants aged >80 were excluded from the analyses because they were not age matched to the comparison group.*  
*p<.05; **p<.01 ***p<.001

**Figure 1:** Boxplots of total gray matter (GM) volume for controls and CKD patients (in ml).
Table 1 also shows baseline characteristics separately for CKD patients with and without elevated depressive symptoms. There were no significant demographic and clinical differences between these groups.

**Total gray matter volumes**
Participants with CKD had a significant 8% lower total GM volume (in ml) compared to controls: 610 (SD=90); 660 (SD=80); p=.04) (figure 1). Depressed and non-depressed participants with CKD did not differ with respect to their total GM volumes (GM volumes: 610 (SD=0.07); 630 (SD=0.10); p=0.63, respectively).

**VBM: CKD versus controls**
In the ROI analyses, four clusters located in the bilateral OFC were observed at the initial voxel threshold at p<.005 and the spatial cluster extent threshold of k>50 (k=384; k=355; k=141; k=114), but these did not survive small volume (SV) correction (Table 2). There were no clusters in the hippocampus and the ACC. Whole-brain VBM analyses did not reveal significant FWE-corrected clusters of reduced GM volume for CKD. However, 12 clusters were observed at the initial uncorrected voxel threshold, most of these were located in the bilateral precuneus and bilateral OFC (supplementary table 1; figure 2A).
**Figure 2:** A. Bilateral clusters in the OFC for CKD compared to controls (N=48; MNI coordinates: -14 62 -18). B. Cluster in the left IFG for depressed versus non-depressed CKD patients (N=24; MNI coordinates: 48 11 3). Images are presented in neurological convention.

**Figure 3:** Boxplots of lesion load for controls and CKD patients. Circles depict mild outliers and asterisks depict extreme outliers (whiskers and boxes represent the four quartiles without outliers).
VBM exploratory analysis: depressed versus non-depressed CKD patients

In the whole-brain VBM analyses examining depression in CKD patients (Table 3), five clusters were observed at the initial threshold (p<.005, k>50). The largest cluster (k=429) was located in the right inferior frontal gyrus (Figure 2B). Two smaller clusters were located in the bilateral OFC (k=92 and k=55). Furthermore, one cluster was located in the inferior temporal gyrus (k=61) and one in the precuneus (k=110). The cluster overlay function of MRIcron showed that clusters found for depressed versus non-depressed CKD patients did not spatially overlap with the clusters found for CKD versus controls.

WMLs: CKD versus controls

CKD patients had more severe pvWMLs than controls (mean: 3.6 [SD:1.9] versus 2.6 [SD:1.3], respectively; F=4.4; p=.04), as shown in Table 4. This was also significant for pvWMLs of the frontal caps (mean: 1.38 [SD:0.71] versus 0.96 [SD:0.69], respectively; F=4.2; p<.05). The presence of scWMLs did not differ between CKD patients and controls (79% versus 63%; p=.20). However, CKD patients had a higher lesion load than controls (mean rank 29 versus 20, respectively; U=183; Z=-2.18; p=.03) (Figure 3). Of note, the boxplot of Figure 3 shows four outliers in the control group, which represent relatively old hypertensive participants. In addition, the two outliers of the CKD group represent relatively old hypertensive patients on hemodialysis. Furthermore, lesion load in the frontal lobe tended to be higher for patients with CKD compared with controls (mean rank 28 versus 21, respectively; U=195; Z=-1.92; p=.05).

WMLs exploratory analyses: depressed versus non-depressed CKD patients

As shown in Table 4, the presence and severity of periventricular and subcortical WMLs was unrelated to the presence of depression.

Table 3: Results for depressed (N=10) versus non-depressed (N=12) CKD patients: uncorrected whole brain analyses, at p<.005, uncorrected; k>50.

k = cluster size (based on voxels of 1.5 x 1.5 x 1.5mm); MNI-coordinate = coordinates of the voxel showing peak significance in mean MNI-space (defined by Montreal Neurological Institute).
This structural neuroimaging study found significantly reduced global GM volume and more severe WMLs in CKD patients compared to age- and sex-matched controls. Moreover, lower regional GM was observed in frontal areas previously associated with CKD, and important for emotion regulation: Robust bilateral clusters were found in the OFC for CKD patients, though effects did not survive proper correction for multiple comparisons. Furthermore, CKD patients had a marginally higher WM lesion load in the frontal lobe compared to controls. In subsequent exploratory analyses comparing depressed versus non-depressed CKD patients, reduced GM clusters were indeed detected in depression-related structures within the frontal lobe. Therefore, the results suggest that frontal lobe pathology in CKD might mediate the increased risk for depressive pathology. Results indicate the need for studies with larger sample sizes in order to objectify the potential role of regional atrophy and WMLs in the relation between CKD and depression.

**VBM findings**

In line with a previous VBM study comparing dialysis patients with controls, we observed that CKD patients had 8% lower total GM volume compared to age- and sex-matched controls. Although all VBM findings were only observed in FWE-uncorrected analyses, we observed relatively large clusters of reduced GM in the bilateral OFC and precuneus for CKD patients compared to controls. Studies of comparable sample sizes reported volumetric reductions of comparable or even smaller magnitude by using less stringent thresholds. Previous studies in CKD patients showed reduced GM clusters in both the precuneus and OFC. However, the precuneus was not included in our ROI analyses and has not

CKD = chronic kidney disease; DEP+ = depressed; DEP- = non-depressed; pvWML = periventricular white matter lesion; scWML = subcortical white matter lesion; M = mean.
consistently been associated with depression.\textsuperscript{39} In contrast, reduced GM volume in the OFC has been consistently found in patients with late-life depression.\textsuperscript{18}

The exploratory VBM analyses showed reduced GM clusters mainly located in frontal brain areas for depressed compared to non-depressed CKD patients. This is in line with the vascular depression hypothesis, which proposes that abnormalities would occur specifically in frontal brain regions.\textsuperscript{14,15} We found reduced GM in the OFC, which is thought to be an important part of networks involved in emotional and cognitive processing.\textsuperscript{40} It is proposed to play a role in decision making and experiencing pleasure and reward, with especially the last function likely to be impaired in depression.\textsuperscript{41} Thus, the observed trends for the bilateral OFC are in line with our initial hypothesis regarding this region as a potential link in CKD and depression. In addition, these observations are in consonance with findings from a previous PET study that found that higher scores on the Hamilton Depression Rating Scale (HDRS) were associated with decreased cerebral glucose metabolism of the OFC in pre-dialysis CKD patients.\textsuperscript{35} Furthermore, GM reductions in the OFC were observed for depressed cardiac patients compared to depressed patients without cardiac disease.\textsuperscript{42} Perhaps, GM abnormalities in the OFC is particularly associated with depression in the context of vascular disease.

The largest and therefore the most compelling cluster of the exploratory analyses was located in the right inferior frontal gyrus (IFG). Previous neuroimaging studies in depression showed GM reductions and abnormal functional activation in the IFG for depressed patients.\textsuperscript{43,44} The right IFG is found to be particularly involved in inhibitory processes.\textsuperscript{45} Although we cannot draw definite conclusions from the exploratory analyses, the observed trends are in line with the suggestion that CKD patients with reduced GM in frontal areas might be more vulnerable for depressive symptoms. This would be interesting to replicate in a larger sample.

**WML findings**

CKD patients had a higher severity of both periventricular and subcortical WMLs than controls, which is consistent with previous studies in CKD patients.\textsuperscript{22,24,28,29} The presence of WMLs was not significantly different between patients and controls (79\% vs. 63\% respectively). This is probably due to the age of the current sample.\textsuperscript{46} We also tested whether periventricular and subcortical WML severity was larger in the frontal lobe for CKD patients compared to controls, as this potentially poses a vulnerability for the onset of depressive symptoms.\textsuperscript{14,25-27} CKD patients had a (borderline) significant larger frontal lesion load compared to controls.

In the subsequent explorations, depressed CKD patients did not differ from non-depressed patients with respect to the presence/absence and severity of WMLs. One explanation may be that WMLs arising in different anatomic locations may relate differently to depression.\textsuperscript{25-27} In the current study we were
unable to examine WMLs with more regional specificity. Instead of quantifying WMLs within the frontal lobe, it would be more specific and sensitive to investigate tract-based WM pathology.\textsuperscript{27,47} Diffusion Tensor Imaging (DTI) for instance, is a method that can detect more subtle impairments to WM tracts and provides the opportunity to study white matter with more regional specificity.\textsuperscript{48}

**Strengths, limitations, and implications for future research**

The strength of this exploratory study is that - to the best of our knowledge - it is the first to assess structural brain abnormalities as a potential factor in the relation between CKD and depressive symptoms. The main limitation of this study is the small sample size, especially for the sub-analyses comparing depressed and non-depressed CKD patients. Consequently, power was limited to detect only relatively large effect sizes. Future research is therefore needed to confirm whether our trends of regional reduced GM in depression-related areas could be replicated in a larger sample. In addition, a larger sample makes it possible to adjust for factors which could potentially confound the results (e.g. educational level and smoking status). However, it is a challenging task to include a sufficient number of CKD patients for MRI research, because of the poor physical condition of many patients and the related MRI-contraindications. Alternatively, meta-analysis of the few existing studies would be valuable in order to examine the relation between CKD and regional brain alterations with sufficient power.

Further, as this was a cross-sectional study, we could not infer causality. In order to examine whether there is a causal pathway from CKD leading to atrophy and WMLs leading to depressive symptoms, or whether brain morphology poses a pre-existing vulnerability, a longitudinal study design is required. Another limitation is that patients with most severe CKD and vascular pathology were possibly underrepresented in the sample, due to MRI incompatibilities. In addition, we included both pre-dialysis and dialysis patients, which potentially hampers the comparison of our results with other studies using more homogeneous patient groups, but which increases generalizability across CKD patients. Of note, whether patients were on dialysis or not, was not associated with differences in brain structure (GM: p=0.33; pvWML: p=0.29; scWML: p=0.77). Finally, total scWML volume was approximated based on a visual rating scale instead of a more objective semi-automated segmentation method to measure WML volume.

**Clinical implications**

If brain alterations would play a role in causing depressive symptoms in CKD patients, this may have important clinical implications. Because of a different depression etiology, patients may be less responsive to traditional depression treatments.\textsuperscript{49} Instead, focusing on the prevention of development and progression of brain damage might be more effective in these patients. Clinicians
should particularly monitor modifiable cerebrovascular risk factors such as smoking, cholesterol levels, and hypertension. Cerebrovascular drugs might slow the progression of brain damage. In addition, anti-inflammatory drugs might be effective to reduce CKD- and dialysis-induced inflammation, thereby preventing the progression of cerebrovascular damage and depressive symptoms. Furthermore, exercise is a promising non-pharmacological intervention that has shown to improve brain structure and function—particularly subcortical-frontal brain areas—as well as cognitive function and depression in older adults. Finally, patients on dialysis should be treated with cooled dialysate, as this provides protection against dialysis-associated brain injury.

**Summary and conclusion**

We examined whether structural brain alterations in CKD patients were located in depression-related areas, and whether these were more pronounced for patients with elevated depressive symptoms. We found that CKD was associated with globally lower GM volumes and higher WML severity. In addition, CKD patients had a marginally higher lesion load in the frontal lobe and we found trends of lower GM volumes in depression-related brain areas, which were more pronounced for patients with elevated depressive symptoms. WMLs were not associated with depressive symptoms, possibly because of the lack of anatomic specificity in the WML ratings.

To conclude, besides the psychological burden of CKD, brain changes may make patients more susceptible for the onset of depressive symptoms. The results imply the need for future (longitudinal) studies with larger samples to objectify whether and which structural brain abnormalities could possibly underlie the relation between CKD and depressive symptoms, as this might have important clinical implications.

Supplementary

Hemodialysis settings
Patients were on conventional bicarbonate dialysis with a low-flux polysulfone (F8, Fresenius Medical Care, Bad Hamburg, Germany) or polyamide (Gambro-Hospal, Lund, Sweden) hollow-fiber dialyser. Blood flow and dialysate flow rates were 250-350 ml/min and 500 ml/min, respectively. Dialysate temperature was 36.0°C or 36.5°C. Dialysate composition was as follows: sodium 139 mmol/l, calcium 1.5 mmol/l, magnesium 0.5 mmol/l, chloride 108 mmol/l, bicarbonate 34 mmol/l, acetate 3.0 mmol/l, and glucose 1.0 g/l. The concentration of potassium was 1.0 or 2.0 mmol/l, depending on prevailing plasma potassium concentrations.
