Introduction

Renal transplantation is the most effective treatment for patients suffering from end-stage renal disease\textsuperscript{1}. Due to the shortage of donors, suboptimal kidneys, such as circulatory death donor (DCD) kidneys, are increasingly used to enlarge the donor pool\textsuperscript{2–4}. Unfortunately, DCD kidneys are more likely to develop ischemia-reperfusion injury (IRI), which can result in short-term complications such as delayed graft function (DGF) or early graft failure\textsuperscript{5,6}. IRI as consequence of a period of warm ischemia prior to organ retrieval is an important impeller of tissue injury in DCD kidneys. The pathogenesis of IRI is complex and involves acute hypoxia in the ischemic phase. Although reperfusion is essential for the reintroduction of oxygen, reperfusion itself causes additional injury due to massive mitochondrial production of reactive oxygen species (ROS), ATP depletion, cytoskeletal dysfunction and intracellular Ca\textsuperscript{2+} accumulation, which subsequently leads to activation of various injury pathways\textsuperscript{7–9}.

ROS production is not only detrimental to cells in many ways, it is an important modulator of protein function as well. It has been shown that elevated levels of ROS drive both matrix metalloprotease (MMP) expression and MMP activation\textsuperscript{10}. More specifically, ROS induces the expression and activation of MMP-2 and MMP-9\textsuperscript{11–14}, two proteases that play a prominent role in acute and chronic renal injury\textsuperscript{15,16}. It has been shown that targeting MMP-9 greatly reduces renal tissue damage after IRI\textsuperscript{14,17}. Doxycycline is a widely used antibiotic that, in addition to its anti-bacterial properties, inhibits MMP-9. MMP-9 exerts protective effects during renal IRI\textsuperscript{18–20}, however, the exact underlying mechanisms are still unclear.

As of 2016, static cold storage (SCS) has been replaced by hypothermic machine perfusion (HMP) as the standard of clinical care in The Netherlands for all kidneys donated by deceased donors. Multicenter randomized controlled trials have shown improved outcome in terms of a reduced incidence of DGF for HMP preserved kidneys compared to SCS\textsuperscript{21,22}. Additionally, trials have shown that oxygenated HMP reduces post-transplant complications and significantly increases the one-year graft survival rate compared to HMP without oxygen\textsuperscript{23}. Besides improved preservation, HMP offers a therapeutic platform during organ preservation.

In this study, we explored the effect of doxycycline on proteolytic degradation mechanisms and urinary proteome of perfused kidney grafts. We performed an in-depth unbiased urinary proteomics and renal tissue degradomics analysis to assess whether doxycycline influences renal function at a molecular level during machine perfusion. Furthermore, we assessed renal function during ex vivo reperfusion, corroborating the altered metabolic, coagulation and complement pathways affected by doxycycline.

Abstract

Ischemia-reperfusion injury (IRI) is a hallmark for tissue injury in donation after circulatory death (DCD) kidneys. The implementation of hypothermic machine perfusion (HMP) provides a platform for improved preservation of DCD kidneys. Doxycycline administration has shown protective effects during IRI. Therefore, we explored the impact of doxycycline on proteolytic degradation mechanisms and the urinary proteome of perfused kidney grafts. Porcine kidneys underwent 30 minutes of warm ischemia, 24 hours of oxygenated HMP (control/doxycycline) and 240 minutes of ex vivo reperfusion. A proteomic analysis revealed distinctive clustering profiles between urine samples collected at T15 minutes and T240 minutes. High-efficiency undecanal-based N-termini (HUNTER) kidney tissue degradomics revealed significantly more proteolytic activity in the control group at T-10. At T240, significantly more proteolytic activity was observed in the doxycycline group, indicating that doxycycline alters protein degradation during HMP. In conclusion, doxycycline administration during HMP led to significant proteolytic and proteolytic differences and protective effects by attenuating urinary NGAL levels. Ultimately, we unraveled metabolic, and complement and coagulation pathways that undergo alterations during machine perfusion and that could be targeted to attenuate IRI induced injury.
Materials and Methods

Experimental design
Porcine kidneys \((n=7)\) were retrieved from a local abattoir and exposed to 30 minutes of warm ischemic time (WIT). Next, kidneys were preserved with oxygenated hypothermic machine perfusion for 24 hours with (DOXY group) or without (control group) the addition of 100 \(\mu\)M doxycycline (Vibramycin SF 100 mg/5ml, Pfizer BV, The Netherlands) at a mean pressure of 25 mmHg at 4°C using 100% oxygenated (100 ml/min) University of Wisconsin machine perfusion solution (Belzer MPS, Bridge to Life) and a Kidney Assist portable (XVIVO, Gothenburg) perfusion machine. Currently the maximum HMP preservation time applied in the clinics in The Netherlands is 24 hours. Thereafter, kidneys were reperfused in an ex vivo normothermic perfusion setup for 240 minutes with a mean arterial pressure of 80 mmHg at 37°C using a custom-made perfusion machine. NMP specifications and analyses are shown in Table S1. Samples were collected throughout HMP and reperfusion for renal function, proteomics and degradomics analysis (Figure 1).

Proteomic analysis of urine using an in-solution digestion
To analyze the effect of doxycycline on the urinary proteome, urine samples collected at timepoint T15, T60, T120, T180 and T240 minutes of \(\text{ex vivo}\) reperfusion were concentrated and resuspended in 100 mM triethylammonium bromide (Merck). Each sample was individually denatured and reduced using 5 mM dithiothreitol and alkylated using 20 mM iodoacetamide. Afterwards, all samples were cleaned up using a methanol-chloroform precipitation, and protein concentrations were determined from Uniprot using MaxQuant 24 with the following parameters: trypsin for enzyme specificity, allowing up to 2 missed cleavages and a minimum peptide length of 6. Precursor mass tolerance at 10 ppm and fragment mass tolerance at 0.05 Da. Samples were normalized against missing data from normal distribution.

Tissue degradome analysis using a TMT-HUNTER workflow
To analyze protein degradation, snap frozen renal cortex tissue was collected before start of reperfusion (T-10) and after 240 minutes of reperfusion (T240) using a 23 mm needle biopsy gun (Invivo, Best, The Netherlands). Proteins were labeled using tandem mass tags (TMT) and prepared according to a high efficiency undecanal N-terminal enrichment (HUNTER) degradomics workflow as described by Weng et al. 26.

In short, tissue was homogenized in RIPA Lysis and Extraction Buffer (ThermoFisher) with 10% sodium dodecyl sulfate (SDS) and Complete Mini EDTA-free Protease Inhibitor Cocktail (Sigma) using Precellys 24 homogenizer (Bertin Instruments). Benzonase was added to degrade all DNA and RNA. Protein concentrations were determined using Pierce BCA Protein Assay Kit (Thermo Scientific). 150 \(\mu\)g of protein per sample was precipitated using acetone-methanol precipitation. Protein pellets were resuspended in 30 \(\mu\)L 0.1 M guanidine hydrochloride, 50 \(\mu\)L nanopure H2O, and 20 \(\mu\)L 1 M HEPES pH 8. Each sample was individually denatured and reduced using 10 mM tris(2-carboxyethyl)phosphine and alkylated using 25 mM iodoacetamide. Whole protein labeling at N-terminal \(\alpha\)-amines site was performed using TMT 11-plex™ isobaric label reagents (Thermo Scientific). Labels were dissolved in anhydrous DMSO equal to sample volume and added to each sample and incubated for 1 hour at room temperature. Samples were then quenched using 25 \(\mu\)L 1 M ethanolamine. Afterwards, all samples were combined creating three sample pools, cleaned up using an acetone-methanol precipitation, and digested using 30 \(\mu\)g of trypsin (Promega) per sample pool for 20 hours. The combined sample was enriched for protein N-termini using 50:1 \(\mu\)L 1 M guanidine hydrochloride, 50 \(\mu\)L nanopure H2O, and 20 \(\mu\)L 1 M HEPES pH 8. Each sample was individually denatured and reduced using 10 mM tris(2-carboxyethyl)phosphine and alkylated using 25 mM iodoacetamide. Whole protein labeling at N-terminal \(\alpha\)-amines site was performed using TMT 11-plex™ isobaric label reagents (Thermo Scientific). Labels were dissolved in anhydrous DMSO equal to sample volume and added to each sample and incubated for 1 hour at room temperature. Samples were then quenched using 25 \(\mu\)L 1 M ethanolamine. Afterwards, all samples were combined creating three sample pools, cleaned up using an acetone-methanol precipitation, and digested using 30 \(\mu\)g of trypsin (Promega) per sample pool for 20 hours. The combined sample was enriched for protein N-termini using 50:1 w/w undecanal and 40 mM sodium cyanoborohydride. Samples were acidified with 0.5% trifluoroacetic acid in 40% ethanol and the undecanal with bound tryptic peptides was removed using 0.1% trifluoroacetic acid in 40% ethanol and SOLA™ HRP Cartridges (Thermo Scientific). Samples were desalted using SOLA™ HRP Cartridges, dried down using vacuum centrifugation and resuspended in 0.1% trifluoroacetic acid. A nano-flow reversed phase chromatography-tandem mass spectrometry analysis (nLC-MS/MS) was performed using an Ultimate 3000 UPLC system coupled to a Q Exactive HF with mass spectrometer (Thermo Scientific) as described previously by Fye et al. 27. In short, samples were separated on an EASY-Spray PepMap RSLC C18 column (500 mm × 75 mm, 2 mm particle size, Thermo Scientific) over a 60-min gradient of 2–35% acetonitrile in 5% DMSO, 0.1% formic acid at 250 nL/min.

Raw data files were searched against a proteome database (Sus Scrofa, 2019) compiled from Uniprot using MaxQuant24 with the following parameters: trypsin for enzyme specificity, allowing up to 2 missed cleavages and a minimum peptide length of 6. Precursor mass tolerance at 10 ppm and fragment mass tolerance at 0.05 Da. Samples were normalized against
corresponding pool. Comprehensival analysis was performed using Perseus v1.6.7.0\textsuperscript{25}. Data was log2(x) transformed, and data was imputed by replacing missing data from normal distribution.

**Visualization and Statistics of proteomics and degradomics data**
Heatmaps were created by Z-scoring for normalization, and hierarchical clustering using Pearson correlation with average linkage for both row and column tree using Perseus. For visualizing the volcano plots, a two-sample T-test was performed using Perseus. GraphPad Prism 7.02 (GraphPad Software, USA) was used for plotting the log2 difference between the doxycycline group and the control group on the x-axis, and the -log10 (p-value) on the y-axis. The cut-off for statistical significance was set for -log10 (p-value) > 1.3. Pathway analysis and functional enrichment of proteins was performed using STRING \textsuperscript{10.5}\textsuperscript{9}, PANTHER\textsuperscript{10}, and Cytoscape 3.8.2\textsuperscript{10}. TopFind\textsuperscript{11} and Merops\textsuperscript{12} were used for predicting and matching proteolytic events to most probable responsible protease for peptides searched against a human proteome database (Uniprot, 2021) as sus scrofa is not supported yet.

### Results

**Kidney urine proteomics and tissue degradomics profiles**
The experimental workflow is shown in Figure 1. We first analysed the urinary proteome. Global analysis resulted in 2,955 identified peptides that were matched to 303 unique proteins at a 1% false discovery rate (FDR).

Next, we analysed the kidney tissue degradome using high-efficiency undecanal-based N-termini enrichment (HUNTER)\textsuperscript{26}. Global analysis resulted in 717 identified peptides, potentially reflecting freshly cleaved N-termini of degradation products. 605 peptides were quantifiable due to labeled N-terminal α-amines. This means that after N-terminome enrichment, 85% of the sample represented the quantifiable degradome. These 605 degradation products belong to 265 unique proteins.

**Doxycycline causes molecular alterations in urine during machine perfusion**
We first analyzed the urinary proteome. Pathway analysis of the 303 identified proteins showed that most of these proteins belonged to metabolic pathways and complement and coagulation cascades. Unsupervised clustering was performed to examine data uniformity. No clustering was observed between the treatment groups, however clustering of urine samples taken at time point 15 minutes was observed (Figure 2A). Expression profiling showed that the addition of doxycycline caused significantly more downregulation of proteins in the urine compared to control at T120, T180 and T240 minutes.

To analyze whether the urinary proteome differs between the beginning and the end of kidney reperfusion, unsupervised clustering using urine samples of T15 and T240 was performed. Distinctive clustering was observed between the two timepoints (Figure 2B). Based on hierarchical clustering of the protein expression, two row clusters were identified. Cluster A consists of 34 proteins that are mostly located in extracellular regions and proteins that play a role in complement and coagulation pathways (Figure 2C).
Doxycycline alters renal degradome

Next, we analyzed the kidney tissue degradome. Unsupervised clustering of identified degradation products was performed to examine data uniformity. No clustering was observed between experimental groups (Figure 3A). Figure 3B shows the degradation products significantly up- and downregulated in the doxycycline group compared to control (Table S2). At T-10, more degradation products were observed in the control group. At T240, more degradation products were observed in the doxycycline group (Figure 3C, Table S3).

At T-10, 72 significant degradation products were identified in the control group (Figure 3D). String pathway analysis showed that the majority of these proteins belonged to metabolic processes. A total of 19 significant degradation products were identified in the doxycycline group (Figure 3E). String pathway analysis showed that the majority of these proteins belonged to oxidative phosphorylation.

At T240, 3 significant degradation products were identified in the control group, namely GPI-anchor transamidase, histone H1t and aquaporin-1 (Figure 3C). 51 significant degradation products were identified in the doxycycline group (Figure 3F). String pathway analysis showed that the majority of these proteins belonged to metabolic processes.

Protease activity in experimental groups

PANTHER protein class analysis of both groups led to the identification of 20 proteases. These proteases belong to cysteine, metallo and serine proteases (Table 1). Using a human database in combination with TopFind31 analysis, responsible proteases for the identified substrates in each sample were predicted. At T-10, 17 substrates could be linked to the responsible protease in the doxycycline group and 15 substrates in the control group (Table 2). At T240, 2 substrates could be linked to the responsible protease in the doxycycline group (Table 2). No predictions could be made for the control group at T240.

These proteins were upregulated at T240. Cluster B consists of 72 proteins that are mostly located in the cytoplasm and play a role in metabolic pathways (Figure 2D). These proteins were upregulated at T15. Figure 2E shows the significant differentially expressed proteins in the urine between the two experimental groups. C1s, TGF-β1, and Calpastatin were significantly more secreted into the urine of kidneys treated with doxycycline.

Protein degradation during ex vivo reperfusion

To characterize the effect of ex vivo reperfusion, the significant differences in degradome pre- and post-reperfusion were analyzed in just the control group. Significantly more proteins were degraded after HMP (T-10) compared to after reperfusion (T240) (Figure 4A). At T-10, 69 degradation products were significantly more abundant. String pathway analysis showed that the majority of these products were intracellular (Figure 4B). At T240, 16 degradation products were significantly more abundant. String pathway analysis showed that the majority of these products were localization proteins (Figure 4C).

Renal function and injury markers during HMP and reperfusion

There were no significant differences observed in renal function during HMP (Figure 5). During reperfusion, urinary neutrophil gelatinase-associated lipocalin (NGAL) levels were significantly lower in doxycycline group at T180 minutes ($p = 0.0430$) and T240 minutes ($p = 0.0044$) compared to control (Figure 5H).

During reperfusion, LDH levels during HMP (U/L) were significantly lower in doxycycline group at T180 minutes ($p = 0.0430$) and T240 minutes ($p = 0.0044$) compared to control (Figure 5H).

During reperfusion, LDH levels in perfusate in U/L during HMP (Figure 5D). Oxygen consumption shown in mL O$_2$/min/100 gr. of kidney weight during reperfusion (Figure 5E).

Gelatinase activity (U/mg) ATP/protein (pmol/ug) were localization proteins ($p = 0.0430$) and T240 minutes ($p = 0.0044$) compared to control (Figure 5H).

During reperfusion, urinary neutrophil gelatinase-associated lipocalin (NGAL) levels were significantly lower in doxycycline group at T180 minutes ($p = 0.0430$) and T240 minutes ($p = 0.0044$) compared to control (Figure 5H).

During reperfusion, LDH levels during HMP (U/L) were significantly lower in doxycycline group at T180 minutes ($p = 0.0430$) and T240 minutes ($p = 0.0044$) compared to control (Figure 5H).

During reperfusion, LDH levels in perfusate in U/L during HMP (Figure 5D). Oxygen consumption shown in mL O$_2$/min/100 gr. of kidney weight during reperfusion (Figure 5E).

Gelatinase activity after 240 minutes of reperfusion. A. Arterial flow during hypothermic machine perfusion (HMP) shown in mL/min/100 gr. of kidney weight over time. B. String clustering and KEGG pathway analysis of degradation products significantly upregulated after reperfusion.
minutes ($p = 0.0297$) compared to control (Figure S1H). When looking at gene expression of fibrosis markers, no significant differences were observed (Figure S1).

**Discussion**

Ischemia-reperfusion injury in renal transplantation is detrimental for the recipient as it can lead to short- and long-term graft failure\(^5\text{-}\text{33}\). Unfortunately, research into targeting IRI as well as identifying novel drug targets is limited. Omics technologies are used for discovering specific molecular processes that play a role in disease\(^34\). The goal of proteomics is to acquire a more global overview by examining as many proteins of a cell as possible, instead of each one individually\(^35\). Proteases such as the MMPs are enzymes that cause protein degradation and therefore play essential roles in biological processes and pathological implications\(^36\). Determining the degradome and responsible proteases can provide molecular clues about the functionality of a biological pathway. In addition, proteases are druggable targets, thereby offering pharmacological intervention strategies to modulate proteolytic pathways\(^37\text{-}\text{38}\). However, generally, endogenous expression levels of proteases and protease inhibitors are low, which makes them challenging to detect efficiently. Weng et al.\(^26\) developed a high-efficiency undecanal-based N-termini enrichment (HUNTER) method for degradome analysis of microscale samples. HUNTER allows mapping of the exact location of the biologically generated N-termini, generated through the cleavage of a peptide bond by the protease that is responsible for this proteolytic activity. Proteomic profiling with the use of mass spectrometry has been widely adapted in medical research including the field of kidney failure and transplantation\(^39\text{-}\text{40}\). Our goal was to observe the effect of doxycycline addition during HMP on renal proteome and degradome during ex vivo normothermic machine perfusion. Furthermore, we explored the general effect of machine perfusion on the renal degradome.

**Protein secretion during ex vivo reperfusion**

Proteinuria is a common phenomenon after renal transplantation and is correlated with post-transplant graft survival\(^41\). Rising urinary protein levels were also observed during ex vivo reperfusion (Figure 5). To our knowledge, urine collected during ex vivo reperfusion has never been thoroughly analyzed. As urine is the direct ultra-filtrate of the kidneys especially in an ex vivo setting, it provides accurate information on kidney functionality. Therefore, we analyzed the effect of doxycycline on urinary proteome. Furthermore, we analyzed the urinary proteome during ex vivo reperfusion. When globally observing the urinary proteome, no clustering occurred between groups. However, when looking per time point, significantly more proteins were secreted in the control group.

**Changes in metabolic pathways**

Interestingly, the urinary proteome of both groups at T15 consisted mostly of proteins belonging to metabolic pathways. Renal cells require high levels of energy due to their ATP-dependent functions like reabsorption and secretion\(^42\). Hypoxic injury during ischemia causes production of ROS\(^43\). Excessive ROS production alters the cellular redox potential and causes impairment in electron transport, energy metabolism and causes ATP depletion. Many of the identified degradation products belong to metabolic pathways as well, indicating that metabolism is disturbed during IRI. Treatment that protects metabolic pathways should therefore be administrated at an early stage of ex vivo machine perfusion.

**Changes in complement and coagulation cascades**

The urinary proteome at T240 of both groups consisted of many proteins belonging to complement and coagulation cascades. It has been shown that the complement system is associated with the inflammatory response to IRI\(^44\text{-}\text{45}\). IRI causes the release of danger-associated molecular patterns (DAMPs), neo-antigen formation, and immune complex formation that then can activate the complement system by any of the three complement pathways\(^46\). Even though the underlying mechanisms are still unclear, complement activation due to IRI contributes to the pathogenesis of renal fibrosis. Significant upregulation of C1s secretion in the urine of the doxycycline group was observed. This could indicate that there is detachment of remnant classical complement attack complexes in the doxycycline group. Interestingly, our group has shown that upregulation of C1s secretion during hypothermic machine perfusion correlates with a good kidney function 1-year post transplantation\(^47\). Furthermore, we identified significant downregulation of C3 degradation products before reperfusion and significant upregulation C3 degradation products after reperfusion (Figure 3B;C). It has been shown that C3 formation, and degradation after complement activation by all three pathways plays a role in renal ischemic injury\(^48\text{-}\text{49}\). Inhibition of complement activation could provide novel therapeutic targets to ameliorate fibrosis during ex vivo reperfusion.

**Protein degradation during ex vivo reperfusion**

Protein degradation plays an important role in physiological functioning of the kidney\(^50\text{-}\text{51}\). Excessive protein degradation can lead to loss of tissue integrity and subsequent loss of renal function. However, lack of protein degradation can lead to the accumulation of proteins and fibrosis formation which in turn can also lead to loss of renal function. The delicate balance between synthesis and degradation is therefore key for renal function. To our knowledge, no studies have focused on protein degradation in a renal transplant setting. We therefore studied protein degradation in our controlled experimental setup. More degradation products were observed in the control group after HMP. These results indicate that the addition of doxycycline
possibly attenuates protein degradation during HMP. Additionally, more degradation products were observed after hypothermic compared to normothermic perfusion. This indicates that degradation products are not all flushed out during HMP and that they are possibly recycled during ex vivo reperfusion for tissue repair.

Proteases as possible molecular targets
The protease class that was most active in both groups were cysteine proteases. Both calpain-1 and 2 were identified during ex vivo reperfusion (Table 1). Calpains play a role in Ca\(^{2+}\) signaling and are activated by accumulated intracellular Ca\(^{2+}\) during ischemia\(^5,52\). Activated calpain-1 and 2 selectively cleave cytoskeletal and membrane proteins\(^5,3\). We observed many degradation products of cytoskeletal proteins after HMP (Figure 4), possibly caused by activated calpains. Furthermore, we identified significantly more urinary secretion of calpastatin in the doxycycline group. Calpastatin is an endogenous inhibitor protein that targets the Calpains\(^3,4\). Previous studies have shown that calpastatin is downregulated in heart and brain tissue after ischemia-reperfusion injury\(^55,56\). Overexpression of calpastatin and thus secretion could potentially have a protective effect against IRI and targeting calpains during NMP could possibly protect the kidney against ischemia\(^57,58\).

TopFind analysis predicted that the identified actin and tubulin substrates were most probably cleaved by Serine protease HTRA2, granzyme M, cathepsin S and caspase 3 (Table 2). Interestingly, research has shown that proteolysis of calpastatin by caspase 3 may regulate calpain activity during IRI\(^59\), suggesting interplay between these proteases, calpastatin and cytoskeletal integrity. The prediction was based on a human database, so validation studies need to be performed to identify the exact responsible proteases.

Meprin α/β metalloproteinases were predicted to be active in both groups. They are extracellular proteases that are involved in connective tissue homeostasis, intestinal barrier function and immunological processes. Dysregulation is associated with acute kidney injury, chronic inflammation and fibrosis\(^60,61\). Targeting meprin α/β metalloproteinases during machine perfusion could therefore potentially benefit the kidney.

Effect of doxycycline
The addition of doxycycline during HMP did not affect renal function during HMP (Figure 5A,B), or attenuate the expression of fibrosis markers (Figure S1). Doxycycline did result in significant attenuation of urinary NGAL levels during ex vivo reperfusion (Figure 5H). NGAL is a protein covalently bound to gelatinase from neutrophils\(^62\). It is an acute tubular damage marker after ischemia, and an early fibrosis marker with a great predictive value of post-transplant function\(^63–66\), indicating that doxycycline does potentially have renal protective effects during HMP. These results are in line with Moser et al\(^67\). They showed that the addition of doxycycline under hypothermic conditions has protective effects on rat kidneys as it attenuated injury markers such as secretion of NGAL and reduction of MMP-2 and MMP-9 activity. Furthermore, Cortes et al\(^20\) 2018 showed that doxycycline treatment attenuated renal injury, and downregulated MMP-2 and -9 levels in rat kidneys. We did not see the same effects on gelatinase inhibition in our porcine kidneys (Figure 5F). This could be due to interspecies differences, or the dose-response and thermodynamics of doxycycline under hypothermic conditions. Furthermore, the enzymatic activity of the MMPs is significantly influenced by temperature\(^68\). As normothermic machine perfusion is now increasingly used, it would be beneficial to analyze whether doxycycline shows more prominent effects under normothermic conditions when the kidney graft is 100% metabolically active\(^42\).

Clinical implementation
Although further studies are needed to confirm whether the addition of doxycycline is beneficial during machine perfusion, the emergence of machine perfusion itself provides opportunities for marginal graft repair by means of ex vivo targeted drug delivery\(^69\). We have identified multiple pathways such as metabolic pathways and complement and coagulation pathways that show upregulated degradation during NMP. Furthermore, we have identified several relevant proteases that would make interesting drug targets during NMP. Ultimately, this novel approach will lead to better short and long-term graft function and improve the patient’s quality of life.

Limitations
We were not able to analyze the effects of doxycycline beyond NMP, as these kidneys were obtained from an abattoir and thus transplantation was impossible. However, our model has shown to be a valid technique for assessment of kidney quality during reperfusion\(^70–75\). Kidneys obtained from waste material provide a great platform to test early hypotheses without the need of laboratory animals, thereby reducing both costs and animals for research.

Unfortunately, many cleavage sites within the proteome are still unidentified, and we could only match a handful of substrates to their possible responsible protease. Especially for proteolytic activity in porcine samples, as the prediction software is currently not compatible for the su scrofa degradome. It would be interesting to unravel all proteases responsible for the identified proteolytic activity. Furthermore, it would be valuable to validate these predictions by spiking the protein of interest with the protease of interest. This way we can see if this protease is really responsible for the identified proteolytic activity.
In addition, this pilot study consisted of a small sample size. Validation using larger groups will be needed to further unravel the underlying pathophysiological pathways of IRI.

**Conclusion**

In conclusion, the addition of doxycycline during HMP led to significant proteomic differences. We unraveled multiple pathways that undergo alterations during machine perfusion. Pathways that could be targeted using ex vivo machine perfusion to attenuate IRI induced injury. Furthermore, we showed that doxycycline administration during HMP shows protective effects by attenuating urinary NGAL levels. More validation studies need to be conducted before implementing doxycycline supplementation during machine perfusion preservation.

Renal function analysis:

LDH & ASAT Concentrations were measured in HMP and NMP perfusate in a routine fashion at the lab of clinical chemistry (UMCG).

Urinary protein concentrations Determined using Pierce™ BCA Protein Assay Kit (Thermo Scientific) according to manufacturer’s instructions.

Urinary NGAL Determined using an ELISA kit (Eurobio, France) according to manufacturer’s instructions.

MMP activity Measured using the Gelatinase (Gelatin Degradation/Zymography) Assay Kit (BioVision) according to manufacturer’s instructions.

Statistics GraphPad Prism 7.02 (GraphPad Software, USA) was used for visualizing data and statistical analyses. Values are shown as means with corresponding standard error of the mean. Continuous variables were plotted over time. Statistical differences between groups for each timepoint were determined using 2 way ANOVA and Fisher’s LSD for multiple comparisons. The cut-off for statistical significance was set at \( p < 0.05 \).

**Figure s1**: Gene expression of SERPINH1, ACTA2, FN1, and TGFβ1 after 240 minutes of reperfusion. Data shown as mean±SEM. DOXY; doxycycline treated. RNA was isolated from needle biopsies using TRIZOL reagent (Invitrogen). Reverse transcription was performed with 11μl RNA, incubated at 70°C for 10 minutes, at 37°C for 50 minutes, and 15 minutes at 70°C. PCR started with 20 seconds at 95°C, followed by 40 cycles of 1 second at 95°C and 20 seconds at 60°C. The plate was measured in the QuantStudioTM 7 Flex Real-Time PCR System (Applied Biosystems). Expression levels were corrected with ACTB as a reference gene (ΔCt) and compared with a pooled control group (ΔΔCt).
