ABSTRACT

Sensory hair cells are known for the exquisite displacement sensitivity with which they detect the sound-evoked vibrations in the inner ear. Here, we determine for the first time a stochastically imposed fundamental lower bound on a hair cell's sensitivity to detect mechanically coded information arriving at its hair bundle. Based on measurements of transducer current and its noise in outer hair cells and the application of estimation theory, we show that a hair cell's transducer current carries information that allows the detection of vibrational amplitudes with an accuracy of the order of nanometers. We identify the transducer channel's molecular gating force as the physical factor controlling this accuracy in proportion to the inverse of its magnitude. Further, we show that the match of stochastic channel noise to gating spring noise implies that the gating apparatus operates at the threshold of negative stiffness.

INTRODUCTION

The main peripheral structure that constitutes the mammalian sense of hearing is the cochlea, a snail-shell shaped cavity in the temporal bone filled with fluid (Dallos, 1996). Sound, via the middle ear, excites these cochlear fluids, which transmit their motion via the organ of Corti to the hair bundles of the sensory hair cells. The hair cells perform the actual mechano-electrical transduction in the ear. They encode the mechanical motion of their hair bundle into a change of the open probability of mechanically-gated transducer channels, resulting in a variation of inward transducer current (Hudspeth, 1989; Fettiplace *et al.*, 2001). This signal, the first electrically coded stage in the signal-processing cascade of the ear, is further transformed by the hair cells, most likely also via electro-mechanical feedback (Hudspeth, 1997; Dallos and Fakler, 2002), and sent to the brain.

From the brain's point of view, the transducer channels thus serve as a window onto the mechanical events in the cochlea, which carry the sound-evoked information. Here, unlike most other approaches in hair cell research, we also follow this information-upstream direction, and determine the accuracy with which the position, X, of a hair bundle can be detected given a certain transducer current, I. Since ion channels have intrinsic stochastic properties that derive from their thermal activation, a specific deflection, X, may result in a range of possible transducer currents. Conversely, in the information-upstream direction, this means that a specific transducer current, I, can result from a range of different deflections of the hair bundle, each having a specific probability of evoking that current. The variance of these deflections will be used here as a measure of accuracy of mechano-electrical transduction.

In addition to this intrinsic channel accuracy, the elastic elements that have to be tensioned to engage the transducer channels' gates will also convey Brownian noise to the channels and consequently will additionally impair the accuracy with which a transducer current can be decoded into the evoking hair bundle deflection, X.

The two-state gating spring model (Howard and Hudspeth, 1988) of mechano-electrical transduction is used to describe the overall accuracy in terms of its gating parameters and thus allows for the identification of the physical limitations of mechano-electrical transduction in hair cells.

MATERIALS AND METHODS

Electro- and mechanophysiology

Experiments were performed on apical-coil outer hair cells obtained from acutely isolated organs of Corti taken from CD-1 mouse pups. Animal procedures were regulated under UK Home Office guidelines.

Transducer currents in response to fluid jet stimulation were measured under whole-cell voltage clamp, using an EPC8 patch clamp amplifier (HEKA, Germany) at a -84 mV holding potential (including a -4 mV liquid junction potential correction). Outer hair cells investigated using the dynamic stimulus protocol (see Data analysis) were obtained between postnatal days 5 and 7 (P5-7). Pipettes were pulled from soda glass and thickly coated with wax. Extracellular solution contained (mM): 135 NaCl, 5.8 KCl, 1.3 $CaCl_2$, 0.9 $MgCl_2$, 0.7 NaH_2PO_4, 2 NaPyruvate, 5.6 D-glucose and 10 HEPES, vitamins and amino acids were added from concentrates (pH 7.5, 306 mOsm/kg). Intracellular solution contained (mM): 137 CsCl, 2.5 $MgCl_2$, 2.5 Na_2ATP, 10 Na_2Phosphocreatine, 5 HEPES, 1 EGTA-NaOH (pH 7.3, 292 mOsm/kg). The contribution of basolateral channels to the measured currents was eliminated by the holding potential used and by the replacement of potassium by caesium in the intracellular solution. The average series resistance was 2.7 ± 0.7 MΩ ($n = 11$) after compensation, the average membrane capacitance was 6.2 ± 0.3 pF ($n = 11$) resulting in a typical noise value of about 1.7 pA^2 integrated over the recording bandwidth, which was corrected for in the noise measurements. The average membrane input resistance was 435 ± 195 MΩ ($n = 11$). Current signals were low-pass filtered with cut-off frequencies at 2.5 or 5 kHz (f_{-3dB}, eight-pole Bessel), which was always below the cut-off frequency imposed on the measurements by the series resistance of the patch.

Hair bundle displacement was measured using a differential photodiode system, which was low-pass filtered ($f_{-3dB} = 5$ kHz, eight-pole Bessel) and recorded simultaneously with the transducer current (Géléoc *et al.*, 1997). The r.m.s. noise due to the displacement measurement technique was about 0.3 nm. Fluid jet stimuli were generated and elicited responses were recorded using a Power 1401 data acquisition board in combination with the Signal software package (CED, Cambridge UK). Generated stimuli were low-pass filtered ($f_{-3dB} = 2$ kHz, eight-pole Bessel). Current and displacement recordings were over-sampled at 50 kHz, to allow a proper analysis of the response envelope of the high frequency component (f_2, see Data analysis). Hair bundle stiffness was measured

in response to force steps as described before (Géléoc *et al.*, 1997) in cells held at -84 mV, at P7 and P19 (see Discussion). All experiments were performed at room temperature (≈ 25° C).

Cramér-Rao bound on transducer accuracy

A discrete version of the Cramér-Rao inequality (Papoulis, 1991; van Trees, 1968) is used to determine a lower bound of the variance of any possible unbiased estimator, $\hat{X}$, of hair bundle displacement, X, from a conditional probability density function $p(I \mid X) = p(n_o \mid X)$. This function expresses the probability of a total transducer current, I, entering the cell through n_o open channels, given a position, X, of the hair bundle's tip. Here, $I = i \cdot n_o$, where i is the current flowing through one open channel. The variance, $\sigma^2_{\hat{X}}$, of the estimator, $\hat{X}$, of the input parameter, X, is then equal to, or greater than the Cramér-Rao bound, σ^2_{min}, which stems from intrinsic channel stochastics described by $p(n_o \mid X)$ according to:

$$\sigma^2_{\hat{X}}(X) \geq \sigma^2_{min}(X) = \frac{1}{\sum_{n_o=0}^{N_{ch}} \left[\frac{d \ln p(n_o \mid X)}{dX} \right]^2 p(n_o \mid X)} = \frac{1}{Inf(X)} \qquad (1).$$

The inverse of $\sigma^2_{min}(X)$ is usually referred to as the information, $Inf(X)$, about X contained in I (Papoulis, 1991), and in this case has dimensions equal to m^{-2}. Assuming a total of N_{ch} equal and independent operational channels, we may use the binomial distribution for $p(n_o \mid X)$ (Colquhoun and Hawkes, 1995). Then, evaluating the right-hand side denominator of Eq. 1 yields for the information:

$$Inf(X) = \frac{N_{ch}(p'_o(X))^2}{p_o(X)(1 - p_o(X))} \qquad (2).$$

Here, $p_o(X)$ is the (average) open probability and $p'_o(X)$ is the derivative of $p_o(X)$ with respect to X. The information as given by Eq. 2 appears to be closely related to an empirically defined integrated-band signal-to-noise ratio of hair cell transduction (Dinklo *et al.*, 2003). In that study it was proposed that a transducer current power signal, S_I, in response to a small bundle displacement power, ΔX^2, around operational position, X, is related to the change of the channel's open probability according to: $S_I(X) = [i\, N_{ch}\, p'_o(X)\, \Delta X]^2$, while the transducer current noise power is given by: $N_I(X) = i^2\, N_{ch}\, p_o(X)\,(1 - p_o(X))$ (Holton and Hudspeth, 1986). Combined with the new identity in Eq. 2, this means that the signal-to-noise ratio of hair cell transduction equals the information times the displacement power of its bundle: $S_I / N_I = Inf\, \Delta X^2$. Conversely, our present result also shows that the

Cramér-Rao bound on the accuracy, $\sigma^2_{\min} = 1/Inf$ (Eq. 1), equals the value of hair bundle displacement power, ΔX^2, that results in a signal-to-noise ratio of the transducer current, *I*, of one ($S_I/N_I = 1$).

Two-state gating spring model

For each channel the basic two-state gating spring model assumes the action of a gating spring, which at one end is driven by the hair bundle and at the other end engages the channel's gate (Howard and Hudspeth, 1988; Markin and Hudspeth, 1995). Thermodynamics then shows that the open probability of the channel, $p_o(X)$, is a sigmoidal function of hair bundle position *X* (Fig. 1a), and can be expressed in terms of the gating spring constant, K_s, and the conformational swing of the channel, *D*, both as measured at the hair bundle's tip: $p_o(X) = [1 + \exp(-K_s D(X - X_0)/kT)]^{-1}$. Here, *k* is Boltzmann's constant, *T* is the absolute temperature and X_0 defines the displacement at which $p_o(X) = 0.5$. The product, $K_s \cdot D$, has been termed gating force, *Z*, (Howard and Hudspeth, 1988) and defines an effective operational range of hair bundle displacements, $\Lambda_{90} = 6kT/Z$, centred at X_0 (Fig. 1a), within which the open probability is about 90% modulated, apart from the effect of adaptation (Eatock, 2000). The model also defines an ensemble averaged stiffness, $K_{ch}(X) = K_s - K_{gc}(X)$, of each spring-channel complex (Fig. 1b). This stiffness thus consists of the gating spring constant, K_s, and in addition includes a displacement dependent reduction, $K_{gc}(X) = Z^2 p_o(X)(1 - p_o(X))/kT$, which is related to the extent of gating and therefore termed gating compliance (Howard and Hudspeth, 1988).

The two-state model, extended to also describe differential engagement (van Netten and Kros, 2000) of the two states, was used to generate fits to the measured data and results (e.g. Figs. 2b, 2c and 2d, solid lines). Differential engagement has been introduced to the description of gating of mechano-electrical transducer channels to account for the finite minimum open probability observed at hair bundle positions more negative than about -50 nm. At these bundle positions gating spring tension is possibly decoupled from the channel's gate.

Data analysis

A dynamic stimulus protocol (double-sine), consisting of a sum of two sine waves ($f_1 \sim 49$ Hz and $f_2 \sim 1563$ Hz), displaced the bundle through a large part of its operational range (Fig. 2a). Using the double-sine protocol, $p_o(X)$ relationships (Fig. 2b) were constructed by low-pass filtering of the current response to obtain the low frequency (f_1) component and its harmonics and displaying them as a

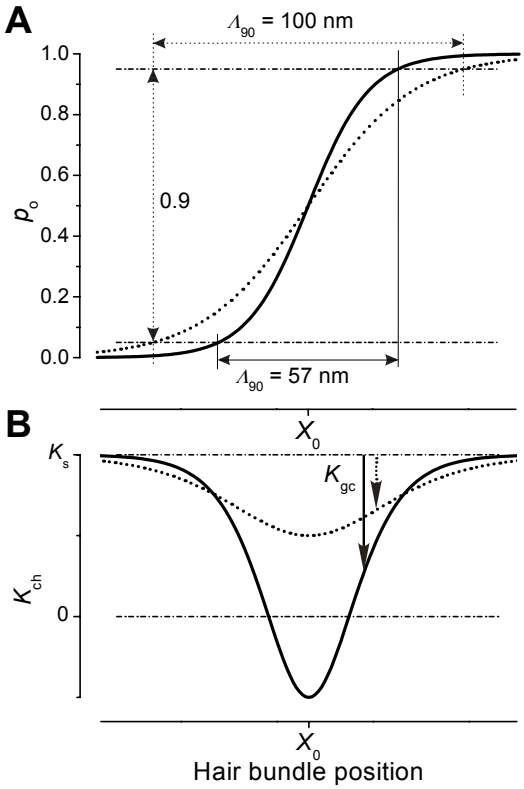

Figure 1. Effects of differing noise contributions on a single gating spring-channel complex. (**A**) open probability, $p_o(X)$, and (**B**) related ensemble averaged stiffness curves, $K_{ch}(X)$, calculated with the two-state model (Howard and Hudspeth, 1988). The gating spring constant, K_s, was fixed (7.5 μN/m) while two different values of parameter D (33 and 57 nm) result in 100 nm (dashed) and 57 nm (solid) for Λ_{90} as indicated via the modulation range of open probability of 0.9. This corresponds to a gating force, Z, of 248 fN (dashed) and 429 fN (solid) respectively. The associated noise matching parameters, M_c^2, are 0.5 (dashed) and 1.5 (solid). In the latter case the intrinsic channel noise, $\sigma_{min}^2(X_0)$, is smaller than the Brownian noise in the gating spring, σ_B^2, and leads to negative values for the stiffness of the gating spring-channel complex in a region around X_0 (see Results). The downward arrows indicate the gating compliances, K_{gc}, at arbitrary X.

function of the associated low-pass filtered hair bundle displacement. The envelope of the remaining f_2 current component was calculated and plotted as a function of the associated displacement component at f_1 to obtain $p_o'(X)$ curves, (Fig. 2c). The two-state model was used to fit the $p_o(X)$ and $p_o'(X)$ data simultaneously. To

match the associated $p_o(X)$ relationships, $p_o'(X)$ data were linearly scaled with a factor (average 0.83 ± 0.09, n = 11), most likely reflecting differences in adaptation (Eatock, 2000) at the two frequencies (f_1 and f_2).

Current noise was determined over about 100 ms time windows during steps of different bundle position, X. Noise power density spectra were determined using Bartlett's periodogram-averaging method (5x averaging), using a Taylor-Kaiser window (β = 1.8) (Fante, 1986).

Unless indicated otherwise, data are presented as the mean ± s.d., with the number of observations in parentheses.

RESULTS

Intrinsic channel stochastics

In the Methods section it is derived how the intrinsic stochastic properties of N_{ch} independent and equal transducer channels with an open probability, $p_o(X)$, limit the accuracy with which a hair cell's bundle position, X, can be optimally detected. This accuracy, or Cramér-Rao lower bound, σ_{min}, is the inverse of the property referred to as information, *Inf*(X), about X contained in I and depends on N_{ch}, $p_o(X)$ and its derivative, $p_o'(X)$, according to Eqs. 1 and 2. The interpretation of σ_{min} as the accuracy of mechano-electrical transduction is further illustrated by the demonstration that σ_{min}^2 equals the bundle displacement power that leads to a transducer current with a signal-to-noise ratio of one (see Methods and Dinklo *et al.*, 2003).

Cramér-Rao bounds on transducer accuracy, $\sigma_{min}(X)$, were determined in 11 apical-coil outer hair cells from simultaneous measurements of transducer current and the position of the hair bundle, which was stimulated with a fluid jet. Figure 2a shows an example of hair bundle displacement (upper trace) and evoked current (lower trace) measured in response to the double-sine stimulus protocol used. This stimulus contained a large amplitude low frequency component (49 Hz, one period shown) and a small amplitude high frequency component (1563 Hz, 32 periods shown). Filtering of the responses enabled the construction of $p_o(X)$ curves from the low frequency components (data points, Fig. 2b). The amplitude of the envelope of the high frequency component in the current response effectively probes the derivative with respect to displacement, X. This allows the independent determination of $p_o'(X)$ curves when plotted against the low frequency component of the displacement (data points, Fig. 2c). The number of operational channels per

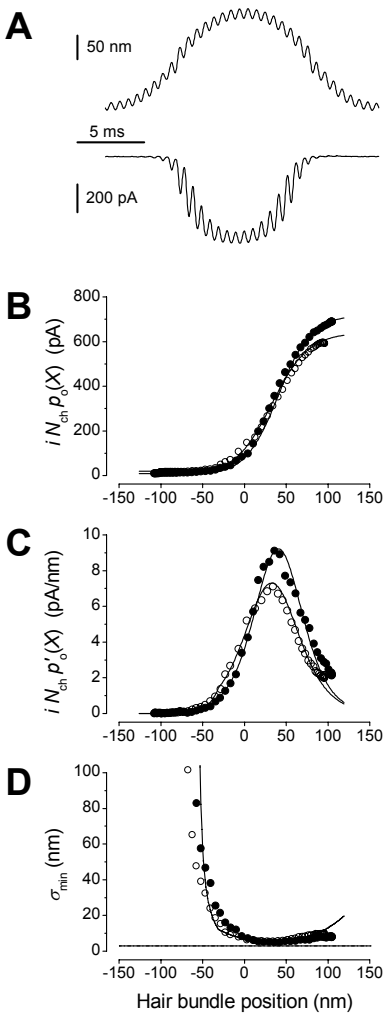

Figure 2. Determination of hair cell accuracy, $\sigma_{min}(X)$. (**A**) Measured hair bundle displacement (Upper) and evoked transducer current (Lower) versus time in response to the double-sine protocol consisting of a large amplitude low frequency (49 Hz) and a small amplitude high frequency (1563 Hz). Traces shown represent averages of 18 responses (bundle height 3.5 μm). (**B**) Transducer current as a function of (quasi-static) hair bundle position, *X*, in two cells obtained from responses as in a (open symbols same cell as in A). (**C**) Changes of transducer currents in response to small changes in hair bundle position normalised to 1 nm as a function of (quasi-static) hair bundle position obtained from the same cells as shown in B. (**D**) Cramér-Rao lower bound on accuracy of hair bundle position, $\sigma_{min}(X)$, determined from the data shown in B and C using Eqs. 1 and 2. Solid lines in panel B-D give results of fits of the two-state gating spring model. Parameters (closed and open symbols respectively): K_s: 6.2, 7.2 μN/m; D: 34, 26 nm; N_{ch}: 74, 66; $\sigma_{min}(X_0)$: 4.5, 5.4 nm; X_0: 41, 33 nm. The horizontal line shows the almost identical (3.0 and 2.9 nm) Brownian gating spring noise levels, σ_B, of the two cells.

cell, N_{ch}, was determined from the saturation current in each cell in combination with the known unitary current (i = 9.7 pA at -84 mV; Géléoc *et al*., 1997). The average value found for N_{ch} was 80 ± 26 (n = 11). Figure 2d shows the resulting lower bound, $\sigma_{min}(X)$, as obtained by substituting N_{ch} and the measured $p_o(X)$ and $p_o'(X)$ data from the same two cells as shown in Figs. 2b and 2c, in Eqs. 1 and 2. The average optimal accuracy, σ_{min}, amounts to 5.9 ± 1.9 nm (n = 11, range 2.9 to 9.9 nm) and is reached at a hair bundle position, X, of 44 ± 18 nm (n = 11). This result thus shows that the intrinsic stochastics of the transducer channels prevents a single outer hair cell to reliably detect mechanical motion of its bundle smaller than the order of nanometers.

Physical limits of transduction

To identify the underlying physics that governs accuracy and related signal-to-noise ratio of hair cell transduction we evaluated *Inf* (Eq. 2) in terms of the gating parameters that define the two-state gating spring model (Howard and Hudspeth, 1988; Markin and Hudspeth, 1995; Materials and Methods). This model was fitted to the measured $p_o(X)$ and $p_o'(X)$ data to obtain the gating parameters for each cell (e.g. solid curves Figs. 2b-2c). Averages of the results are given in Table 1. The gating spring model can be considered the most concise quantitative description to date of observations on the transducer channel's gating machinery and allows a straightforward interpretation in terms of its physical parameters. The most important parameter is the elementary gating force, *Z,* defined as the product of the gating spring constant, K_s, and the conformational swing of the channel, *D*.

Combining the properties of the two-state gating spring model with Eq. 2 reveals that each transducer channel of a hair cell contributes an amount of information, ΔInf , to the total information, $Inf = N_{ch}\,\Delta Inf$, equal to:

$$\Delta Inf = Z^2 \frac{p_o(X)(1-p_o(X))}{(kT)^2} = \frac{K_{gc}}{kT} \qquad (3).$$

The right-hand side of Eq. 3 offers a useful but also profound insight into the process of mechano-electrical transduction: the amount of information, ΔInf, on hair bundle position conveyed by each transducer channel via its gated current, is equivalent to the gating compliance, K_{gc}, divided by the thermal noise energy, *kT*. Nonlinear distortion in hair bundle mechanics, caused by gating and characterised by the gating compliance, K_{gc} (see Materials and Methods), therefore appears to be inevitable for information transfer. The amount of information is fundamentally constrained by the level of thermal noise energy. It is obvious from Eq. 3 that the information is maximal at $X = X_0$ ($p_o(X_0) = 0.5$), where it amounts to $[Z/(2kT)]^2$ so that the optimal accuracy in estimating the hair bundle's position per channel, $\sigma_{min}(X_o)$, is $2kT/Z$. This theoretical result, with our average experimental value on *Z* (174 ± 60 fN, $n = 11$), leads to about 47 nm per channel and, for 80 ± 26 operational channels, to 5.3 ± 2.6 nm per cell. This is in line with the result for the optimal σ_{min} (5.9 nm), directly obtained from substituting the experimental results obtained for N_{ch}, $p_o(X)$ and $p_o'(X)$ in Eqs. 1 and 2 (Fig. 2d).

When increased, the gating force, *Z,* seems to limitlessly improve accuracy ($\sigma_{min} = 2kT/Z$) and related signal-to-noise ratio of a hair cell. At the same time,

Table 1. Main parameters used. Values in the second column, when given, were obtained from fitting the two-state gating spring model to the measured data.

Symbol	Value, unit	Description
I	pA	Transducer current
X	nm	Bundle displacement at the tip
$p_o(X)$		Transducer channel open probability
$Inf(X)$	m^{-2}	Information about X contained in I
S_I	pA^2	Transducer current power signal
N_I	pA^2	Transducer current power noise
M_c	0.50 ± 0.16	Noise matching parameter
N_{ch}	80 ± 26	Number of transducer channels per cell
X_0	44 ± 18 nm	Bundle displacement at which $p_o = 0.5$
σ_{min}	5.9 ± 1.9 nm	Intrinsic channel noise (Cramér-Rao bound)
σ_B	2.8 ± 0.6 nm	Gating spring noise
Λ_{90}	156 ± 50 nm	Operational range of transduction
D	23 ± 7 nm	Conformational swing of the channel
Z	174 ± 60 fN	Gating force
K_s	7.4 ± 1.0 μN/m	Gating spring constant
$K_{ch}(X)$	μN/m	Stiffness of a single gating-spring channel complex
$K_{gc}(X)$	μN/m	Gating compliance
$K_{ngc}(X)$		Gating compliance normalised to K_s

though, this would reduce the effective operational range, $\Lambda_{90} = 6kT/Z$, within which hair bundle vibrations are predominantly transduced (p_o is modulated about 90% within Λ_{90}, see Methods and Fig. 1a). The requirement for a hair cell to transduce the physiological range of hair bundle vibrations, therefore, undoubtedly puts an upper limit on the value of the gating force. The ratio of operational range, Λ_{90}, and optimal accuracy, $\sigma_{min}(X_0)$, defines an upper bound on the dynamic range of transduction per channel, which can now easily be inferred to amount to a factor of 3 (≈ 9.5 dB) and is surprisingly independent of any parameter of the model. The operational range, Λ_{90}, of an ensemble of identical but independent channels is the same as that of one channel. However, increasing the number of channels to N_{ch} improves their collective optimal accuracy to $2kT/\left(Z\sqrt{N_{ch}}\right)$, thereby increasing a hair cell's effective dynamic range to $9.5+10\log(N_{ch})$ dB. Together with the average number of operational channels found ($N_{ch} = 80$), this

leads to a theoretical dynamic range of about 28.5 dB. This dynamic range is consistent with the ratio (28.4 dB) of the average operational range, Λ_{90} (156 ± 50 nm, n = 11), and $\sigma_{\min}(X_0)$ (5.9 nm), both directly obtained from our experimental data.

Gating spring noise

So far we have only considered signal-to-noise ratio and accuracy arising from intrinsic channel stochastics, which, therefore, are solely related to transduction. However, noise attacks the mechano-transducer system on multiple fronts. At its input, formed by the gating springs, the system is also susceptible to Brownian noise fluctuations. When completely transduced, the Brownian noise of a gating spring evokes a current per channel equivalent to the current evoked by a hair bundle stimulus variance of $\sigma_B^2 = kT/K_s$ (Landau and Lifshitz, 1980). Since we find from our data a value for K_s of 7.4 ± 1.0 μN/m (n = 11), σ_B equals on average an equivalent stimulus of about 24 nm for a single channel. Like $\sigma_{\min}$, this gating spring noise also scales down in proportion to the inverse of the square root of the total number of channels, yielding σ_B = 2.8 ± 0.6 nm (n = 11) per cell. In the stimulus domain, the variance induced by the gating spring noise, σ_B^2, can be expected to add independently to the lower bound on the variance, $\sigma_{\min}^2$, as obtained from the Cramér-Rao inequality.

How do these two noise components compare? Using Eqs. 1-3, together with $\sigma_B^2 = kT/K_s$, yields:

$$\frac{\sigma_B^2}{\sigma_{\min}^2(X)} = \frac{K_{gc}(X)}{K_s} = K_{ngc}(X) \qquad (4).$$

The ratio of the two noise components thus equals the gating compliance, K_{gc}, normalised to the gating spring constant, K_s, and is denoted here as $K_{ngc}(X)$. Given a gating spring constant with associated $\sigma_B^2 = kT/K_s$, a smaller summed variance could be obtained by adjusting the gating force so as to reduce $\sigma_{\min}^2(X_0)$. Reducing it considerably more than the inescapable level of σ_B^2 would, however, not pay off since σ_B^2 would continue to dominate the summed variance, while the operational range would, unfavourably, decrease. On the basis of these considerations, we hypothesise that a hair cell, at $X = X_0$, may operate at closely matched noise levels ($\sigma_{\min}^2(X_0) \approx \sigma_B^2$), from which it follows that the normalised gating compliance, $K_{ngc}(X_0)$, should be of the order of one (Eq. 4). Interestingly, this condition is equivalent to each gating spring-channel complex operating close to the threshold of negative stiffness ($K_{ch}(X_0) \approx 0$) as is obvious from the

definitions of K_{ch} and K_{ngc} (Methods and Eq. 4). A characteristic matching parameter, M_c, can therefore be defined according to: $M_c^2 = \sigma_B^2 / \sigma_{min}^2(X_0) = K_{ngc}(X_0) = K_s D^2 / (4kT)$. If M_c exceeds one, a region of negative stiffness of the spring-channel complex exists (Fig. 1b) and gating spring noise predominates. If, on the other hand M_c is smaller than one, stiffness is positive and intrinsic channel noise dominates, while if M_c is one the two noise components in the stimulus domain exactly match at X_0, and $K_{ch}(X_0) = 0$.

To test the noise matching hypothesis ($M_c \approx 1$), we determined M_c in outer hair cells using K_s and D resulting from fits to our data (Table 1). The average value obtained for M_c is 0.50 ± 0.16 (n = 11) and shows that the two components of noise at X_0 are indeed comparable, as is also apparent from the examples in figure 2d by comparing the data on $\sigma_{min}(X_0)$ (4.5 and 5.4 nm) to the horizontal lines representing σ_B (3.0 and 2.9 nm respectively).

DISCUSSION

Two noise contributions, intrinsic channel stochastics and gating spring noise, both affecting the primary process of mechano-electrical transduction in hair cells were quantified. These contributions amount to the order of nanometers, when interpreted in terms of equivalent hair bundle noise (σ_{min} and σ_B). The optimum accuracy arising from intrinsic channel stochastics is reached at a deflection, X_0, about 45 nanometer positive of the equilibrium position of the hair bundle, as measured under our experimental conditions (Fig. 2d). Extracellular calcium concentrations, such as found in the cochlear endolymph (~30 μM, (Bosher and Warren, 1978)) have been shown to bring X_0 close to the equilibrium position (Crawford *et al.*, 1991), via a calcium mediated process called adaptation (Eatock, 2000). This process is therefore a likely candidate to maintain optimal detection accuracy under equilibrium conditions.

On the basis of the hypothesis of matched noise variances in the stimulus domain ($\sigma_{min}^2 \cong \sigma_B^2$) we have demonstrated that the ensemble averaged stiffness of a gating spring-channel complex of a hair cell becomes negative, a property that has been reported previously in saccular hair cells (Martin *et al.*, 2000). An unequivocal direct experimental observation in the stimulus domain of the degree of matching of the contributions of mechanical gating spring noise and intrinsic channel noise is beyond present experimental possibilities. However, the transducer current noise should reflect both components of the variance in the stimulus domain. We therefore analysed current noise measurements to investigate

whether they were consistent with the inferences made from our analysis on intrinsic channel noise and the noise-matching hypothesis.

Figure 3 shows the variance of the current noise measured at different positions of the operational point, *X*, of the hair bundle. It is compared with noise variances (solid lines) predicted on the basis of fits of the gating spring model to the cell's measured $p_o(X)$ and $p'_o(X)$ data (e.g. Figs. 2b and 2c). The prediction of the total noise variance (solid line I), consisting of the sum of the channel stochastics (solid line II, $N_{ch}\, i^2 p_o (1 - p_o)$) and gating spring noise (solid line III, $N_{ch}\, i^2 (p'_o)^2 \sigma_B^2$), adequately follows the shape of the measured noise as a function of hair bundle position, *X*. However, the predictions were systematically higher than the actually measured noise with a fixed factor per cell (8.8 ± 3.8, $n = 4$). The most likely explanation for the lower noise variance measured is that the low-pass filter used cuts off the high frequency part of the spectrum, producing the predicted shape as a function of *X*, but at a fixed fraction. The steepest roll-off part of the spectrum of the measured noise power (Fig. 4) indeed follows the high frequency roll-off of the low-pass filter used (solid line), indicating that the intrinsic cut-off frequency of the transducer channels is beyond the cut-off frequency of the low-pass filter. This is in line with measured current responses to steps having rise-time constants that were found to be limited by the time constant of the stimulus device used (≈ 50 μs, not shown) corresponding to rate-constants of the channel exceeding

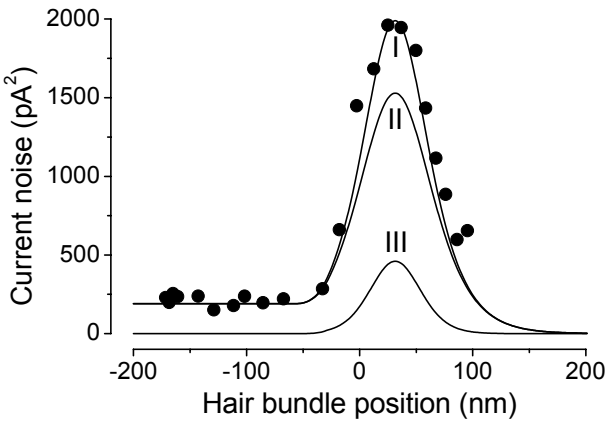

Figure 3. Current noise variance as a function of operational position of the hair bundle. Measured data points of this cell were multiplied (fixed factor 12.3) to fit the summed noise (solid line I) predicted from intrinsic channel stochastics (solid line II, $N_{ch}\, i^2 p_o (1 - p_o)$) and gating springs (solid line III, $N_{ch}\, i^2 (p'_o)^2 \sigma_B^2$), using the fitted parameters describing the measured open probability and its derivative (e.g. Figs. 2b and 2c).

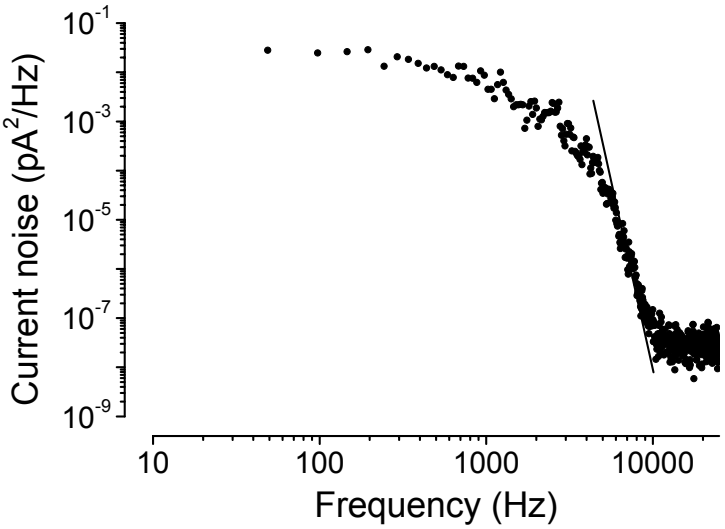

Figure 4. Current noise power spectrum. Current noise spectrum obtained at X = 25 nm showing that the high frequency roll-off equals that of the eight-pole Bessel filter used (solid line, 48 dB/oct), indicating that the intrinsic cut-off frequency of the channels is beyond the cut-off of the filter.

3 kHz. Figure 3 shows that at negative hair bundle positions (< ≈ -50 nm) the scaled data are in agreement with the differential engaging of the two states, implying a small but constant (≈ 1%) open probability in that range. The related constant noise in this range excludes the possibility that the noise due to the gating springs (solid line III) greatly dominates the stochastic channel noise of the cell (solid line II). The scaled measurements are consistent with the predicted ratio of the two noise components of $M_c (= \sigma_B / \sigma_{min} = 0.55)$ for this cell. Three other cells were analysed and gave similar results. Mechanical noise of the whole non-stimulated hair bundle was measured directly and found to be less than 4 nm^2. This is consistent with the Brownian noise expected from a hair bundle with stiffness of the order of mN/m (Géléoc *et al.*, 1997; Fante, 1986). In the stimulus domain, whole hair bundle noise of outer hair cells is therefore about an order of magnitude smaller than the average summed noise of the gating springs, σ_B^2 (7.6 nm^2), and intrinsic channel noise, $\sigma_{min}^2(X_0)$ (34.2 nm^2). Neglecting the whole hair bundle noise, this results in an overall optimal accuracy in the detection of hair bundle position amounting to $\sqrt{\sigma_B^2 + \sigma_{min}^2(X_0)}$ = 6.5 ± 2.0 nm (n = 11).

An alternative explanation for the apparent lack in measured noise variance

that cannot be completely ruled out on the basis of the present experiments is that the ensemble of N_{ch} operational channels of a cell may, dependent on the stimulus, effectively split up in sub-ensembles with different open probabilities, leading to a lower noise variance than expected from N_{ch} independently fluctuating channels. Such a noise-reducing mechanism may be effected by a feedback mechanism per channel, for instance Ca^{2+}-binding to the channel (Fettiplace *et al.*, 2001; Hudspeth, 1997), and could thereby improve the cell's signal-to-noise ratio. If the observed noise reduction factor (8.8) would completely arise from such a mechanism, $\sigma_{min}(X_0)$ would decrease with a factor $\sqrt{8.8}$ and the best overall accuracy in detecting hair bundle motion (6.5 nm) would be improved by just a factor of 2 leading to 3.4 nm. Channel interaction like the co-operative scheme proposed in a recent study (Iwasa and Ehrenstein, 2002), is not likely to decrease the channel noise but instead can be expected to increase it. This can be appreciated from considering the channel noise of $N_{ch}/2$ independent pairs, each consisting of two fully co-operating channels, thus effectively having twice the conductance of a single channel.

Other types of hair cells than the outer hair cells considered here might have different bundle mechanics and gating parameters resulting in alternative relative contributions of the individual noise sources. It has been reported that in frog saccular hair cells bundle noise may dominate (Denk and Webb, 1992) and it has been suggested that this may serve the phenomenon of stochastic resonance (Jaramillo and Wiesenfeld, 1998). Also, the ratio of gating spring noise and intrinsic channel noise ($\sigma_B / \sigma_{min} = M_c$) may vary, possibly related to the specific detection function of a hair cell. Mammalian vestibular hair cells, for instance, may possess spring-channel complexes with an M_c exceeding one (van Netten and Kros, 2000). Results reported on turtle hair bundle nonlinearity (Ricci *et al.*, 2002) show that M_c in these cells exceeds 0.75, whereas data on fish lateral line hair cells (van Netten, 1997) indicate a value of at least one. A recent report on transduction in frog saccular hair cells (Martin *et al.*, 2000) translates into an M_c of about 1.5. The associated collective negative stiffness of the gating springs in those hair cells may even dominate the positive passive stiffness of the hair bundle that results from its pivots in the apical plate and stereociliary side-to-side links, rendering the isolated hair bundle as a whole unstable within a substantial region ($\approx$ 20 nm). Evidence from outer hair cells so far indicates that their hair bundle's stiffness is dominated by positive passive contributions (van Netten and Kros, 2000).

What limit is imposed on the threshold of hearing by the noise of the gating

apparatus of the transducer channel we considered? First we have to consider whether our results from neonatal hair cells are representative for those in the mature hearing organ. It has recently been demonstrated that transducer channel properties of outer hair cells in rats do not obviously change with the onset of hearing (Kennedy *et al.*, 2003). We found the steady-state bundle stiffness of transducing mature hair cells at P19 (3.9 ± 1.2 mN/m, $n = 7$) to be about 25 % less than the stiffness at P7 (5.1 ± 2.0 mN/m, $n = 7$). Both values are comparable to previous results from neonatal cochlear cultures (Géléoc *et al.*, 1997; van Netten and Kros, 2000). The absolute reduction in hair bundle stiffness exceeds the overall gating spring contribution (van Netten and Kros, 2000) and is therefore most likely related to a reduction in the bundle's passive stiffness resulting from structural changes of the bundle or the disappearance of the kinocilium during this stage of development. The latter possibility is in line with a previous report on a relative kinociliary contribution to the whole bundle stiffness of 10-25% (Rüsch and Thurm, 1990). Both possibilities would not directly affect the mechano-electrical transduction process but could lead to displacement noises scaled up with the same percentage. Also, no signs of spontaneous hair bundle oscillations were found during the neonatal (P7) or the hearing stage (P19). We may thus assume that similar transduction-related noise variances as reported here apply to the hair cells in the mature hearing organ, including the inner hair cells, which most likely possess very similar transduction characteristics (Kros *et al.*, 1992).

From our results we arrive at a displacement variance of $(6.5)^2$ nm^2 contained within a bandwidth of at least 5 kHz. This corresponds to an upper bound of about $9 \cdot 10^{-2}$ nm/(Hz)^{½} as a bandwidth-independent inaccuracy per outer hair cell and could be even a factor of about 3 lower if the hair cells transduce one order of magnitude faster (50 kHz). Whatever the further signal processing mechanisms, the inaccuracy set by the elastic engagement of hair cell transducer channels cannot be circumvented. Obviously, the threshold in terms of a minimal detectable displacement by a single hair cell may be improved at the expense of the effective bandwidth. Lowering it for instance down to the range of tens to hundred Hertz would enable a single outer hair cell, if no further noise is added in the filtering process, to match the lowest reported threshold of hearing, which in different organs ranges from fractions of a nanometer to several nanometers (Crawford and Fettiplace, 1983; Robles and Ruggero, 2001). This same threshold, however, may also be obtained within a larger bandwidth if more than one hair cell contributes to the signal processing. Therefore, a combination of ensemble averaging across

several hair cells and a limited effective bandwidth effected by passive electrical and mechanical filtering, as well as active electro-mechanical feedback whether mediated by the hair bundle or by prestin (Hudspeth, 1997; Dallos and Fakler, 2002), would seem required to reach the exquisite displacement threshold that some hearing organs possess.
