**ABSTRACT**

Transmission is a main route for bacterial contamination, involving bacterial detachment from a donor and adhesion to receiver surfaces. This work aimed to compare transmission of an extracellular polymeric substance (EPS) producing and a non-EPS producing *Staphylococcus epidermidis* strain from biofilms on stainless steel. After transmission, donor surfaces remained fully covered with biofilm, indicating transmission through cohesive failure in the biofilm. Counter to the numbers of biofilm bacteria, the donor and receiver biofilm thicknesses did not add up to the pre-transmission donor biofilm thickness, suggesting more compact biofilms after transmission, especially for non-EPS producing staphylococci. Accordingly, staphylococcal density per unit biofilm volume had increased from 0.20 to 0.52 μm$^{-3}$ for transmission of the non-EPS producing strain under high contact pressure. The EPS producing strain had similar densities before and after transmission (0.17 μm$^{-3}$). This suggests three phases in biofilm transmission: (1) compression, (2) separation and (3) relaxation of biofilm structure to its pre-transmission density in EPS-rich biofilms.

**Introduction**

Biofilms consist of bacteria adhering to the surface of a substratum, embedded in a matrix of extracellular polymeric substances (EPS) (Flemming and Wingender 2010; Hall-Stoodley et al. 2012). The structure of a biofilm can differ depending on the substratum surface and not only impacts the penetrability of the biofilm by nutrients (Nadell et al. 2009; Sjollema et al. 2011), but also by antimicrobials (Stewart and Costerton 2001; Donlan and Costerton 2002). Moreover, the viscoelasticity conveyed by the EPS matrix hampers detachment of biofilms by mechanical means (Stoodley et al. 2002; Flemming and Wingender 2010; Peterson et al. 2015). As a consequence, biofilms cause major problems in many different and widely varying environments, such as on biomaterial implants and devices (Hall-Stoodley and Stoodley 2005; Campoccia et al. 2013; Lebeaux et al. 2013), ships’ hulls (Flemming 2002; Tribou and Swain 2015), water transport pipes (Juhna et al. 2007; Rhoads et al. 2016) and food packaging materials (Li et al. 2009; Nerín et al. 2016). Biofilm formation can be described by four distinct phases (Rendueles and Ghigo 2012): (1) transport from an aqueous suspension or air towards a substratum surface (Donlan and Costerton 2002; Nadell et al. 2009; Sjollema et al. 2011); (2) reversible adhesion to the substratum surface; (3) transition of an adhering organism from a planktonic to a sessile phenotype, producing EPS to cause irreversible adhesion; and (4) growth.

Although it is mostly assumed that transport occurs through convective-diffusion in an aqueous suspension or air, in many practical situations bacteria are transmitted from one surface to another under an applied contact pressure (Zapka et al. 2011). Transmission is an essentially different process from transport by convection or diffusion because it involves detachment of adhering bacteria from a donor surface followed by subsequent adhesion to a receiver surface (Van der Mei et al. 2010; Qu et al. 2011). Transmission is one of the main routes of bacterial contamination occurring in biomedical, domestic, environmental and industrial applications, either under compressive or shear loading of a biofilm-covered donor and an initially clean receiver surface. Bacterial transfer from urethral epithelial cells to urinary catheters for
instance, occurs mainly under shear (Warren 2001; Siddiq and Darouiche 2012), while transmission between gloves from healthcare workers, the skin of a patient and hospital equipment occurs predominantly under compressive loading (Morgan et al. 2012). The epidemiological consequences of bacterial transmission between surfaces in hospital environments are amply studied and it is known that bacterially contaminated surfaces in hospital environments increase patients’ risk of infection (Vickery et al. 2012; Cheng et al. 2015). Mechanisms of bacterial transmission, on the other hand, are seldom studied. Importantly, due to the involvement of a load during transmission, transmission may affect the structure and therewith the nutrient and antimicrobial penetrability of biofilms left-behind (Donlan and Costerton 2002; Nadell et al. 2009; Sjollema et al. 2011) on donor surfaces which are transmitted to receiver surfaces.

It was the aim of this study to compare biofilm transmission of Staphylococcus epidermidis ATCC 35984 (an EPS producing strain) and S. epidermidis 252 (a non-EPS producing strain) between two stainless steel surfaces under compression by applying two different contact pressures. Donor biofilm thicknesses before and after transmission as well as biofilm thicknesses on the receiver surfaces after transmission were determined using optical coherence tomography (OCT). Subsequently, the numbers of bacteria in donor and receiver biofilms were enumerated in a Bürker–Türk counting chamber after biofilm dispersal. In addition, biofilms were imaged using confocal laser scanning microscopy (CLSM) and two-photon-laser scanning microscopy (2P-LSM) (Neu et al. 2002). EPS production was inferred from the presence of calcofluor white staining in fluorescent images of stained biofilms.

Materials and methods

Bacterial strains and growth condition

EPS producing S. epidermidis ATCC 35984 (Williams and Bloebaum 2010) and non-EPS producing S. epidermidis 252 were originally isolated from a patient with a catheter-associated sepsis and stool (Van der Mei et al. 1997), respectively. Both strains were grown aerobically for 24 h at 37°C on blood agar plates from frozen stocks. One single colony was used to make a pre-culture in 10 ml of tryptone soya broth (TSB, Oxoid, Basingstoke, UK) supplemented with 0.25% D(+)glucose, anhydrous (C6H12O6, Merck, Darmstadt, Germany) and 0.5% NaCl (Merck), which was incubated for 24 h at 37°C. This 10 ml pre-culture was used to inoculate a second culture of 200 ml supplemented TSB, which was incubated for 16 h at 37°C and used for further experiments. The number of staphylococci in the culture suspension was 1 × 10^9 bacteria ml⁻¹, as measured using a Bürker–Türk counting chamber.

Preparation of stainless steel surfaces and biofilm formation

Biofilm transmission was carried out between stainless steel 304 (SS) donor and receiver surfaces. SS plates with a surface area of 2.25 cm² (15 mm × 15 mm; 1 mm thickness) were cleaned by rinsing with 2% Extran® (Merck) followed by sonication for 5 min in 2% of RBS™35 (Sigma-Aldrich, St Louis, MO, USA) and rinsing with tap water, 70% ethanol and finally sterile, demineralised water. This yielded a water contact angle of 27 ± 4°.

In order to improve staphylococcal adhesion, the SS surfaces were first coated with serum proteins by immersion in 10% foetal bovine serum (FBS) (F7524, Sigma-Aldrich) in phosphate buffered saline (PBS) for 2 h under static conditions. After pipetting out the FBS solution, the FBS-coated stainless steel donor plates were placed on the bottom of Petri dishes filled with 15 ml of a staphylococcal suspension and left to allow bacterial adhesion for 1 h at 37°C. Next, the suspension was carefully removed after which the plates were placed into a Petri dish with 15 ml of fresh supplemented TSB medium. Subsequently, staphylococci were grown for 48 h at 37°C to form a biofilm. The medium was refreshed after 24 h.

For transmission and biofilm analysis, medium was pipetted carefully out of the Petri dishes and biofilm-covered plates were placed into a new Petri dish with 10 ml of reduced transport fluid, pH 6.8 (RTF; NaCl 12 g l⁻¹, (NH₄)₂SO₄ 12 g l⁻¹, KH₂PO₄ 6 g l⁻¹, MgSO₄·7H₂O 2.5 g l⁻¹, K₂HPO₄ 6 g l⁻¹, Na₂EDTA·2H₂O 41.2 g l⁻¹, L-cysteine. HCl·H₂O 11.1 g l⁻¹) to enable transport of the biofilm-covered plates to either of the instruments for biofilm characterisation.

Biofilm transmission assay

First, for ease of handling, cork cylinders were glued to the backsides of the receiver plates. For transmission, RTF was pipetted out of the Petri dish and a SS receiver was pressed on top of the biofilm covered donor surface under a pressure of 0.7 or 7.0 kPa for 1 min. The pressures chosen are in the same range as the pressure of holding a cup of coffee or using a door handle, being around 2 kPa (Arinder et al. 2016). Next, donor and receiver surfaces were rapidly (<1 s) and perpendicularly separated from each other by keeping the donor plate in place with a pair of forceps and simultaneously lifting the receiver plate. Subsequently, both receiver and donor plates were immersed in RTF for further experiments. All experiments were carried out in triplicate with different staphylococcal cultures and samples. The numbers of staphylococci in the biofilm before and after transmission were determined by dispersal of the biofilms over the entire substratum area of 2.25 cm², using sterilised, 5 mm interdental brushes (Albert Heijn,
Zaadnam, the Netherlands) in 5 ml of RTF while remaining in their Petri dishes. After brushing, the brush, plate and the RTF were put in a sterile tube and sonicated for 1 min to remove bacteria from the brush and plate and break bacterial aggregates. Subsequently, staphylococci were enumerated in a Bürker–Turk counting chamber. Staphyloccocal transmission was expressed as a log-reduction of the number of bacteria on the donor plates according to:

\[10 \log (D_0 - R) - 10 \log (D_0)\]

in which \(D_0\) is the number of staphylococci on the donor plate before transmission and \(R\) the number of bacteria found on the receiver after transmission.

**OCT analysis of biofilms**

The biofilms were analysed before transmission on the donor plates and after transmission on both donor and receiver plates with an OCT Ganymede II (Thorlabs Ganymade, Newton, NJ, USA), while keeping the plates immersed in the RTF. The biofilms were analysed on basis of 10 line scans on each donor and receiver plate by image post-processing of each line scan using Image J (National Institutes of Health, Bethesda, MD, USA), covering the entire substratum area of 2.25 cm². First, the bottom of the biofilm was determined as the best fitting line (second order polynomial) that connects the white pixels resulting from light reflection on the substratum surface. Subsequently a grey-value threshold that separates the biofilm from the background was calculated on basis of the grey-value histogram of the entire image (Otsu 1979). Then the upper contour line of the biofilm was defined as those pixels in the image that have a grey value just higher than the grey-value threshold and are connected to the bottom of the biofilm by pixels with grey values all higher than the grey-value threshold. The mean biofilm thickness per line scan was calculated based on the number of pixels between the bottom of the biofilm and the upper contour line. The overall biofilm thickness was defined as the average biofilm thickness over 10 line scans.

**Confocal laser scanning microscopy and two-photon laser microscopy**

LIVE stain (BacLight™, Molecular probes, Leiden, the Netherlands) containing SYTO9 (3.34 mM) was applied to the biofilms for 15 min in the dark at room temperature, followed by staining with fluorescent brightener 28 (50 mM) (Calcofluor white M2R; Sigma, St Louis, MO, USA) for 15 min to visualise EPS. It should be noted that calcofluor white only stains polysaccharides within an EPS matrix, as a main matrix component next to eDNA, proteins and possible other molecules. After staining, the biofilm was immersed in PBS and imaged using a CLSM (Leica TCS-SP2, Leica Microsystems Heidelberg GmbH, Heidelberg, Germany) at 40× magnification with laser excitation at 488 and 351 nm for SYTO9 and fluorescent brightener 28 staining. Imaging was performed using a Zeiss LSM 7MP microscope (Zeiss, Jena, Germany) with Chameleon Vision compact OPO two photon laser (Coherent, Santa Clara, CA, USA). Excitation wavelengths of 825 nm were used and an emission filter set at 470–515 nm for SYTO9 or 435 nm for fluorescent brightener 28. Images were acquired and analysed using ZEN-lite imaging software (Carl Zeiss, Jena, Germany).

**Statistical analysis**

The differences in biofilm properties before and after transmission were compared using two-tailed Student’s t-test. Differences were considered significant if \(p < 0.05\). Statistical analysis was performed using GraphPad Prism version 7.00 (GraphPad Software, La Jolla, CA, USA; www.graphpad.com).

**Results**

**Staphyloccocal biofilms on SS donor surfaces before transmission**

Biofilms on SS surfaces fully covered the substratum surface and showed clear patches of calcofluor white stainable EPS in biofilms of *S. epidermidis* ATCC 35984, that were absent in biofilms of *S. epidermidis* 252 (Figure 1a). Topological imaging of the biofilms using 2P-LSM revealed mushroom-like structures in biofilms of EPS producing *S. epidermidis* ATCC 35984, while biofilms of the non-EPS producing strain were relatively smooth without mushroom-like structures (Figure 1b). This topological difference was confirmed in low-resolution, cross-sectional OCT images of biofilms (Figure 1c), showing a smaller thickness of 48 ± 9 μm for the EPS producing than for the non-EPS producing strain (70 ± 14 μm). Dispersal and subsequent microscopic enumeration of bacterial numbers in a biofilm indicated that *S. epidermidis* ATCC 35984 biofilms contained 7.4 × 10⁸ bacteria adhering cm⁻² of substratum surface, while this number was twofold higher in biofilms of *S. epidermidis* 252 (14 × 10⁸ bacteria cm⁻²). A combination of
possessed a more granular structure, with small black regions indicative of water-filled regions (Wagner et al. 2010; Blauert et al. 2015), opposite to more homogeneously grey-looking biofilms of non-EPS producing \textit{S. epidermidis} 252.

Table 1 summarises the qualitative and quantitative features of both staphylococcal biofilms before transmission.

Transmitted biofilms on receiver surfaces were generally too thin for a comprehensive analysis of their features. Bacterial densities are averaged over three separately grown biofilms out of different cultures with ± indicating SDs. Asterisks indicate significant differences between densities before and after transmission.

these bacterial numbers per unit area with the thicknesses measured in OCT provided bacterial densities per unit biofilm volume, which were slightly lower before transmission in biofilms of the EPS producing staphylococcus (0.15 μm⁻³) than of the non-EPS producing staphylococcus (0.20 μm⁻³). In addition, the OCT images of \textit{S. epidermidis} ATCC 35984 biofilms possessed a more granular structure, with small black regions indicative of water-filled regions (Wagner et al. 2010; Blauert et al. 2015), opposite to more homogeneously grey-looking biofilms of non-EPS producing \textit{S. epidermidis} 252.

Table 1 summarises the qualitative and quantitative features of both staphylococcal biofilms before transmission.

**Staphylococcal biofilms on SS donor surfaces after transmission**

OCT images (Figure 2a and b) clearly show that the donor surfaces after transmission remained fully covered with biofilm, while the receiver surfaces show patchy coverage after transmission of *S. epidermidis* ATCC 35984 and only a very thin film after *S. epidermidis* 252 transmission. Donor biofilms of EPS producing *S. epidermidis* ATCC 35984 were flattened during transmission, and mushroom-like structures, as observed on donor biofilms before transmission, had disappeared. OCT images for both staphylococcal strains looked more homogeneously grey and sharper confined than before transmission (compare Figure 1c with Figure 2a and b). After transmission of EPS-producing *S. epidermidis* ATCC 35984, elongated structures could be seen in 2P-LSM micrographs on the donor biofilms of *S. epidermidis* ATCC 35984.

**Figure 2.** Examples of cross-sectional OCT images of staphylococcal biofilms of EPS producing *S. epidermidis* ATCC 35984 (a), and (b) non-EPS producing *S. epidermidis* 252 on SS donor and receiver surfaces after transmission at an applied pressure of 0.7 kPa for 1 min. Scale bars = 100 μm. (c, d) Surface topography from 2P-LSM (colours indicate the local height of the biofilm as indicated by the pseudo-colour bars) of biofilms on the SS donor surfaces after transmission for EPS producing *S. epidermidis* ATCC 35984 (c) and (d) non-EPS producing *S. epidermidis* 252 (right panel) at a pressure of 0.7 kPa. Arrows indicate elongated structures.
biofilm thickness on the donor before transmission, suggesting either loss of biofilm during the transmission process or structural changes induced during transmission. Significant loss of bacteria from the biofilms during transmission can be ruled out however, because the numbers of bacteria on donor and receiver surfaces after transmission did add up to the numbers of bacteria counted on donor surfaces before transmission (Figure 3c and d).

A combination of biofilm thicknesses and numbers of bacteria in biofilms per unit area on donor surfaces after transmission shows (see Table 1) that after transmission,
the biofilm densities per unit volume of *S. epidermidis* ATCC 35984 on the donor surfaces were similar (0.15–0.20 μm⁻³) before and after transmission (biofilms on receiver surfaces were too thin and heterogeneously distributed for these kind of calculations). However, after transmission under the high pressure, bacterial densities in biofilms of the non-EPS producing *S. epidermidis* 252 increased significantly from 0.20 to 0.52 μm⁻³.

**Discussion**

Transmission is a common pathway for bacterial contamination of surfaces in diverse environments. In this paper, the structure of staphylococcal biofilms between a SS donor and a receiver surface before and after transmission were compared. Regardless of EPS production, ie calcofluor white stainable matrix components, donor surfaces remained fully covered with biofilm after transmission, which indicates that transmission occurred through cohesive failure in the biofilm since donor biofilms left behind were thinner than before transmission. EPS played a crucial role in restoring the structure of biofilms after transmission, which is proposed to be regarded as a three-phase process, involving: (1) compression of the biofilm under the applied contact pressure, (2) separation exerting a tensile stress on biofilm inhabitants and (3) relaxation (Table 2). Each of these three phases will be discussed in the next subsections.

**Compression**

The first step in bacterial transmission between surfaces is compression of the biofilm between the donor and receiver surfaces by an external contact pressure. Water along with dissolved EPS components will be squeezed out first, as it has the lowest viscosity (Peterson et al. 2013). Also, bacteria will redistribute themselves slowly to new, energetically favourable positions. As a net result, bacteria will come closer together and the biofilm will become more compact. Evidence for compaction during the compaction phase is indirect, as biofilms cannot be imaged or analysed when compressed between two plates. However, the higher bacterial densities in biofilms of the non-EPS producing strain after transmission under a contact pressure of 7 kPa can only have arisen during this compaction phase. Compression under a contact pressure 0.7 kPa for 1 min may be too small to yield compaction. Stress–strain diagrams for oral streptococci have a linear elastic trajectory for strains < 0.4, corresponding roughly with a stress of 0.1 kPa, which is in the same range as 0.7 kPa (Paramonova et al. 2009). Partly irreversible compaction up to 50%, however, was observed in biofilms generated in a cross-flow filtration model system by applying a transmembrane pressure in the order of 40–100 kPa (Dreszer et al. 2014). These findings confirm that a critical difference in biofilm response is realistic to expect between contact pressure of 0.7 and 7 kPa, as seen in this paper.

**Separation**

Separation subjects the compacted biofilms to a tensile pressure, ultimately leading to detachment. Detachment occurs relatively rapidly and can either result from failure at the donor–biofilm interface or cohesive failure within the biofilm. Since, after transmission, donor surfaces remain fully covered by biofilm regardless of the strain involved, this indicates that biofilm is transmitted through cohesive failure within the biofilm and subsequent attachment of detached biofilm to the receiver surface. The separation phase is also difficult to visualise in between two plates. However, the presence of collapsed EPS threads on the surface of biofilms of the EPS producing staphylococcal strain, and their absence on biofilms of the non-EPS producing strain, suggest their formation during separation. In contrast to solids under tensile strength, where fracture occurs after the yield point, viscoelastic materials show necking or thinning, which may be the origin of the collapsed threads observed after separation for the EPS-producing strain (Alpkvist et al. 2006). Dunsmore et al. (2002) described a very similar yet distinctly different process for biofilms grown under high and low flow, showing formation of so-called ‘streamlined’ biofilm clusters under high flow.

**Relaxation**

All biofilms, but especially EPS containing biofilms, relax after application of stress, regardless of whether compressive or tensile (Stoodley et al. 1999; Guélon et al. 2011; Peterson et al. 2015), to restore biofilm structure as much as possible. Usually, different components of a biofilm relax with their own characteristic time constants. After transmission as studied here, full restoration of biofilm structure has not been observed depending on the strain considered. In biofilms with more viscous components, relaxation occurs more swiftly (Alpkvist et al. 2006) than in the case of more rigid biofilms (Peterson et al. 2013) and accordingly the more viscous, EPS producing staphylococcal strain used in this study recovered its bacterial density to a higher degree than the more rigid biofilms of the non-EPS producing strain. The non-EPS producing strain demonstrated lasting structural changes that were most evident from the doubling of the bacterial density in *S. epidermidis* 252 donor biofilms after transmission under high contact pressure (7 kPa). The EPS matrix in *S. epidermidis* ATCC 35984 biofilms, on the other hand, facilitated recovery of the bacterial density to pre-transmission values.
The arguments above rely in part on the calculation of bacterial densities in the biofilms. Such calculations have been made possible through the use of OCT, enabling reliable determination of biofilm thickness over much larger areas than can be done with microscopic techniques, usually comprising a field of view of only several hundreds of square micrometres. In OCT, biofilm thickness can be obtained over several square centimetres. In combination with the number of bacteria in a biofilm per unit substrate area, thickness then yields the volumetric bacterial density in a biofilm. Bacterial densities in a biofilm have not been frequently reported in the literature, although they are very helpful for extracting structural data from them in a simple but unequivocal way. Distances between individual bacteria in a biofilm range between 1 and 3 μm (Drescher et al. 2016). Microbial volume fractions in biofilm models have been calculated to range from 0.1 to 0.2, corresponding with bacterial densities between 0.2 and 0.4 μm$^{-3}$ (Wanner and Reichert 1996; Roberts and Stewart 2004). Experimentally obtained dry weights of ~60 mg cm$^{-3}$ of 50 to 100 μm thickness biofilms (Bishop et al. 1995) combined with published bacterial mass densities (Loferer-Krössbacher et al. 1998) yielded a bacterial density of around 0.3 μm$^{-3}$. These data show that the bacterial densities obtained using OCT thicknesses and bacterial numbers after biofilm dispersal are all realistic, both before and after transmission. Importantly, after transmission of the non-EPS producing strain, bacterial densities remained well below the closest hexagonal packing of a 1 μm diameter sphere for which a bacterial density of 1.5 μm$^{-3}$ can be calculated. From this, it can be concluded that staphylococci are not yet compressed to their maximum density under a contact pressure of 7 kPa. Whereas non-EPS producing S. epidermidis 252 was unable to recover from this compaction due to the lack of a visco-elastic matrix, S. epidermidis ATCC 35984 recovered to its pre-transmission density of around 0.18 μm$^{-3}$.

In conclusion, this paper introduced a three-phase biofilm transmission model, in which EPS plays a crucial role in defining the structure of biofilms after transmission. Transmission occurs through cohesive failure in the biofilms and after transmission, compacted biofilms can relax from the compression phase to their pre-transmission structure utilising the viscoelasticity of their EPS matrix.
