Objective: To explore the long-term outcomes of CONECSI (COping with NEuropathic Spinal cord Injury pain), a multidisciplinary cognitive behavioural treatment programme in persons with spinal cord injury.

Design: Long-term follow-up pre-post-intervention design.

Subjects: A total of 29 subjects with a spinal cord injury and chronic neuropathic pain from 4 Dutch rehabilitation centres.

Methods: Primary outcomes were pain intensity and pain-related disability (Chronic Pain Grade questionnaire). Secondary outcomes were mood (Hospital Anxiety and Depression Scale), participation in activities (Utrecht Activities List), and life satisfaction (Life Satisfaction Questionnaire). Random coefficient analysis was used for the analyses of measurements before (t1), immediate post-intervention (t2), and 6 (t3), 9 (t4), and 12 (t5) months follow-up.

Results: The analyses showed significant improvements on pain intensity (t1–t2 and t1–t5) and pain-related disability, anxiety and participation in activities (t1–t2, t1–t3, and t1–t5).

Conclusion: This exploratory study suggests that a multidisciplinary cognitive behavioural programme might have lasting improvements on pain intensity, pain-related disability, anxiety, and participation in activities in people with chronic neuropathic spinal cord injury pain and highlights the potential of such programmes.

Key words: spinal cord injuries; neuralgia; chronic pain; longitudinal studies; intervention studies; cognitive therapy.

INTRODUCTION

Spinal cord injury (SCI) is a serious condition and adjusting to the physical and psychosocial consequences of SCI is a great challenge for the person involved (1). The prevalence of depression and anxiety is elevated in people with SCI (2), and their average life satisfaction is substantially below that of the general population (3). Chronic pain is one of the major consequences of SCI and affects about 70% of this population (4). One type of pain many people with SCI have to cope with is chronic neuropathic spinal cord injury pain (CNSCIP), which strongly affects daily functioning and is associated with depression, anxiety and overall quality of life (5–7). A review showed that no less than 40% of persons with SCI reported intense neuropathic pain (4). Neuropathic pain is initiated by a primary injury to the nervous system and involves abnormal sensations, such as burning, electrical and shooting sensations, and often reduced touch sensation and allodynia (8). The mechanisms underlying CNSCIP are only partly understood, and it is still unclear why some SCI patients develop neuropathic pain and others with apparently similar injuries do not (9).

CNSCIP is difficult to treat (10). Approaches that have been used to treat CNSCIP include pharmacological treatments (e.g., anticonvulsants, antidepressants, opioids, or non-steriodal anti-inflammatory drugs) and non-pharmacological treatments (e.g., physical methods, massage, psychological treatments, acupuncture, physiotherapy and exercise). However, to date none of these provide sufficient relief in the majority of the SCI population (11–14). Therefore, there is a need for effective treatments for CNSCIP.

In recent years more attention has been given to psychological treatments because research showed relationships between psychological factors and maintenance and aggravation of CNSCIP (7, 15). Psychological treatment is targeted on pain cognitions, e.g., catastrophising, pain-related beliefs and coping, and social factors, to improve psychological and physical functioning in persons with chronic pain (16). Intervention studies examining the potential for such comprehensive, cognitive behavioural therapy (CBT)-based treatment programmes to benefit persons with SCI and pain showed promising results (17–20), in terms of changes in anxiety (17, 19, 20), and depression (17, 20).

In response to these findings, the CONECSI (COping with NEuropathic Spinal cord Injury pain) trial was conducted to
evaluate the effectiveness of a comprehensive, multidisciplinary cognitive behavioural programme for coping with CNSCIP (21). This randomised controlled trial demonstrated a short-term decrease in both primary outcome measures (pain intensity and pain-related disability) and 2 out of 4 secondary outcome measures (anxiety and participation in activities), although compared to the control group no short-term treatment effect was found for pain intensity and only a trend was found for pain-related disability (p = 0.059) (22). However, the duration of follow-up was restricted to 3 months post-intervention. A long-term follow-up might have shown stronger favourable effects of cognitive behavioural treatment if people get more experience in applying principles learned in the programme in their daily life. To our knowledge, except from one study (17), data on the long-term outcomes of cognitive behavioural interventions for CNSCIP is lacking to date.

The objective of this study was therefore to explore the long-term outcomes of the CONECSI trial. The hypothesis was that the intervention would result in a long-term decrease of pain intensity and pain-related disability, and in improvement of mood, participation in activities, and life satisfaction.

METHODS

Study design

The CONECSI trial is an unblinded multicentre randomised controlled trial. Participants were randomly allocated to an immediate intervention group or to a waiting list control group within each participating rehabilitation centre. The control group was invited for the programme after a waiting period of 6 months. Measurements were performed in both groups before starting the programme (t1), immediately after intervention (t2), and at 6 months (follow-up, t3). These results have been published earlier (22). Since a waiting-list control group was used in this trial, it was possible to perform additional follow-up measurements in the intervention group at 9 (t4) and 12 (t5) months after the start of the intervention. But these long-term measurements were not possible in the control group within the time frame of the study. Therefore only the participants in the intervention group are included in the current long-term follow-up study.

Ethical considerations

The Medical Ethics Committees of the University Medical Centre Utrecht and the participating rehabilitation centres have approved the study protocol. Written informed consent was obtained from each participant. The trial is registered in the Dutch Trial Register (NTR1580).

Study population

Participants were recruited from 4 Dutch rehabilitation centres with a specialisation in SCI rehabilitation: De Hoogstraat Rehabilitation, Utrecht, Adelante Zorggroep, Hoensbroek, Rehabilitation Center Het Roessingh, Enschede, and Rijndam Rehabilitation Center, Rotterdam. Eligible persons met the following inclusion criteria: (1) SCI (determined by the physiatrists of the 4 SCI departments of the rehabilitation centres); (2) at least 18 years old; (3) at least 1 year after discharge from first inpatient SCI rehabilitation; (4) main pain type is neuropathic pain; (5) duration of neuropathic pain at least 6 months; and (6) pain intensity score in the previous week of at least 40 on the 0–100 numerical rating scale of the Chronic Pain Grade (23). Exclusion criteria were: (1) SCI caused by metastatic tumour; (2) previous CBT for coping with CNSCIP; Two theoretical models were used in the programme, the BioPsychoSocial (BPS) model (24) and the Activating event-Belief-Consequence (ABC) model (25). These two models were explained in educational sessions and in guided group discussions using fictitious cases. These models were applied in sports workshops and homework assignments. Further elements of the programme were: information on SCI and CNSCIP; goal setting; information by a physiatrist specialised in SCI rehabilitation and a physiatrist specialised in chronic pain rehabilitation; information on movement and pain; information on assertiveness and communication about pain; introduction to relaxation exercises; information on pain, mood, and stress; and information on social aspects and partner, family, and friends. A detailed description of the study protocol and the CONECSI trial has been reported elsewhere (21).

Instruments

Pain intensity and pain-related disability were measured with the Chronic Pain Grade questionnaire (CPG) (23). Participants rated their pain intensity on a Numeric Rating Scale for mean pain, worst pain, and current pain (pain intensity score 0–100), and the degree of pain interference with daily activities, work/household activities, and recreational/social activities (pain-related disability score 0–100). The internal consistency for the pain intensity score and the pain disability score in an SCI population was excellent (Cronbach’s α 0.95 and 0.94, respectively) (7). In the present study, the CPG has been adapted to ask for neuropathic pain (“The following questions relate to neuropathic pain due to spinal cord injury”) in the past week instead of the past 6 months. The mean of the CPG scores at inclusion and at t1 score was used as the baseline (t1) score (22).

Anxiety and depression were measured with the Hospital Anxiety and Depression Scale (HADS) (26). The HADS is a 14-item self-report measure. It contains 7-item scales: one for anxiety and one for depression, both with a score range of 0–21. It is a valid and reliable measure and responsive to change (26). Woolrich et al. (27) reported a good internal consistency in an outpatient population with SCI, with a Cronbach’s α of 0.85 for the anxiety and 0.79 for the depression scale. Participation in activities was measured with Utrecht Activities List (UAL) (28, 29). The UAL is a Dutch adaptation of the Craig Handicap Assessment and Rating Technique (CHART) (30). Participation in activities is assessed by the time spent on activities such as paid work, study, housekeeping, voluntary work, hobbies, and sports in hours per week.

Life satisfaction was measured with the Life Satisfaction Questionnaire (LiSat-9) (31, 32). The LiSat-9 consists of a global item ‘life as a whole’ and 8 domain-specific items: ‘activities of daily living’, ‘leisure’, ‘vocational situation’, ‘financial situation’, ‘sexual life’, ‘partnership relationship’, ‘family life’, and ‘contacts with friends’. These 9 variables are rated on a 6 point scale (very dissatisfying to very satisfying), with higher scores reflecting greater satisfaction. The internal consistency of the total score (mean of all item scores) was good (Cronbach’s α of 0.80) in a Dutch SCI population (33).

Demographic characteristics assessed at baseline were age, gender, educational level, and marital status. Functional independence was as-
sessed with the Barthel Index (BI) (34). The Dutch translation showed good validity and reliability (Cronbach’s alpha 0.87) in people with SCI (35). Type of pain (musculoskeletal pain; visceral pain; spasm pain; neuropathic pain below, above, or at injury level; pain from syringomyelia; and non-SCI related pain) was assessed by self-report, as well as time post injury, cause of injury, and level and completeness of the lesion. The questions of the DN4 (36) were used to check for the presence of neuropathic pain. The DN4 questionnaire is a validated instrument with a specificity for detecting neuropathic pain of 82.9% and a sensitivity of 89.9% (36).

Neurological lesion level was defined as the highest motor level. Completeness was distinguished in motor complete (AIS grades A and B) versus motor incomplete (AIS grades C and D). Neurological levels below T1 were defined as paraplegia, neurological levels at or above T1 were defined as tetraplegia. The physiatrist was asked if there was any doubt about the patient’s answer about the type of pain or the neurological lesion level, or if the answer was missing. Cause of injury was differentiated into traumatic (traffic, work, and sports accident; fall from height; surgery; and other) and non-traumatic SCI (35). Type of pain (musculoskeletal pain; visceral pain; spasm; neuropathic pain below, above, or at injury level; pain from syringomyelia; and non-SCI related pain) was assessed by self-report.

Statistical analyses
Participant’s characteristics were calculated at t1 (baseline). The pain intensity score and the pain-related disability score of the CPG, the anxiety and depression score of the HADS, total participation in activities of the UAL, and the life satisfaction sum score of the LiSat-9 were calculated for the measurements t1 to t5. Descriptive statistics were computed using means (standard deviations (SDs)). The courses of the outcomes of the intervention over time were analysed using random coefficient analysis (multilevel analysis) (37). The hierarchy in the data of this study is the repeated measurement “time” (t1–t5) (level 1), which is grouped within the individual subjects (level 2), who are grouped in the rehabilitation centres (level 3). Six models were calculated, each with one of the outcome measures as dependent variable (pain intensity, pain-related disability score, anxiety, depression, total participation in activities, and life satisfaction) in a multilevel regression analysis and time modelled with 4 dummy variables (t1–t2, t1–t3, t1–t4, t1–t5) as the determinant. The intercept or slope is fixed, unless the −2 log likelihood of the model with a random intercept or slope is significantly lower (the model is better) then the −2 log likelihood of the fixed intercept or slope model.

Statistical analyses were performed using SPSS statistical program for Windows (version 19.0) and MLwiN program of the Centre for Multilevel Modelling, Institute of Education, University of London (version 2.25). Significance was set at a p-value less than 0.05.

RESULTS

Participants characteristics
A total of 31 persons were randomised in the intervention group of the CONECSI trial. Two persons were excluded from the current analyses because they could not participate in the programme due to health problems before the start of the programme. The mean age of the participants at t1 was 56.5 years (SD 12.1). The median time between the onset of SCI and inclusion was 5.4 years (range 1.9–23.7) and the median duration of CNSCP at inclusion was 4.5 years (range 1.6–23.7). The mean Barthel Index score was 12.7 (SD 5.8) on a 0–20 scale. The mean number of self-reported pain types was 2.5 (SD 1.2). More men than women participated in this study, and the majority had a traumatic SCI, paraplegia, and lived with a spouse (Table I).

Course of primary and secondary outcome measures
Table II shows descriptive data of pain intensity, pain-related disability, participation in activities, anxiety, depression, and life satisfaction at each measurement time-point.

Multilevel analysis showed that pain intensity significantly decreased between the time periods t1–t2 and t1–t5, and that pain-related disability decreased between the time periods t1–t2, t1–t4 and t1–t5. The decrease in pain-related disability between t1 and t3 was just outside significance (Table III, Fig. 1). No changes over time were found for the secondary outcome measures HADS depression and life satisfaction (Table IV). HADS anxiety scores significantly decreased and UAL scores significantly increased across t1–t2, t1–t3, and t1–t5 (Table IV and Fig. 2).

Beta ($\beta$) stands for a non-standardised regression coefficient in multilevel analyses.

---

Fig. 1. Pain intensity score and pain-related disability score of the Chronic Pain Grade questionnaire.
The present study shows that the CONECSI intervention, a multidisciplinary cognitive behavioural programme for coping with CNSCIP, had favourable long-term outcomes on the primary outcomes pain intensity and pain-related disability, and the secondary outcomes anxiety and participation in activities. This study adds long-term outcomes (at 9 and 12 months) to the earlier reported short-term results of the CONECSI trial (22).

Overall, there was no significant difference between the scores at 12 months and the scores immediately after intervention (t2; 3 months), confirming the hypothesis that improvements during the intervention would be maintained at follow-up, although the patterns of scores were variable over time for 3 of the 6 outcome variables. Only pain intensity showed a further decrease after the end of the intervention at 12 months. Although the scores changed in the right direction, no significant change over time was found for depression and life satisfaction. This is in line with the previously reported short-term results (22).

Long-term outcomes
A decrease of pain intensity is usually not a focus of cognitive behavioural programmes, but it is a common “side effect” of improvements in physical and psychological functioning (16). In this study we indeed found a decrease in pain intensity, together with improvements in pain-related disability, anxiety, and participation in activities. This study confirms the conclusions of earlier studies (17, 19) that comprehensive psychosocial pain treatment programmes are promising treatment options for persons with disabilities and pain.

Norrbrink Budh et al. (17) found also change of anxiety and no change in life satisfaction after the intervention, but in contrast to our study they found change of depression, and no change in pain intensity at 12 months follow-up. Nicholson Perry et al. (19) found a reduction in anxiety in their treatment group, and a trend towards improvement on pain intensity and depression at 1 month post-treatment, but the depression scores returned to pre-treatment levels at 9 month follow-up. Both anxiety and depressed mood were addressed in our CBT programme, but maybe it is easier to modify feelings of anxiety than depressed mood by CBT. Life satisfaction was measured using a questionnaire on satisfaction with various life domains, including satisfaction with vocational situation and sexual life, which might explain the lack of change of life satisfaction scores in this study. Dorstyn et al. (38) found in a meta-analysis that most treatment effects of CBT for the management of psychological outcomes following SCI were minimal or not sustained at follow-up. The results of the current study showed little relapse, maybe because of the booster session 3 weeks after the final group session. Nevertheless, further attention for relapse prevention is required (19). Booster session(s) or comeback session(s) in the third to ninth month after finishing the intervention might be helpful.

Implications
Our findings highlight the potential of cognitive behavioural programmes to learn people with SCI cope with neuropathic pain. Our finding of a long-term decrease of pain intensity needs confirmation, but it is encouraging and might make the CBT approach more attractive to patients. The programme focussed on CNSCIP, but it can easily be adapted to include other types of pain. CBT is easy to implement in clinical practice, since it is an accepted treatment in other diagnostic groups. More research is needed on treatment modalities, i.e. individual or group, or internet-based, and on timing, i.e. soon after persons with SCI start experiencing neuropathic pain, or...
only after pharmaceutical and non-pharmaceutical treatments show insufficient pain relief.

ACKNOWLEDGEMENTS

The authors would like to thank the participants in this study, the participating Dutch rehabilitation centres, and the co-trainers in these centres: Lilian Pfnnings (De Hoogstraat Rehabilitation, Utrecht); Conny Overduive (Adelante Zorggroep, Hoensbroek); Wim van de Vis (Rehabilitation Center Het Roessingh, Enschede); Hilde Schors and Nicole Vrijens (Rijnland Rehabilitation Center, Rotterdam).

This study was performed within DALI for PAIN, a national programme that focuses on neuropathic pain care optimisation. DALI for PAIN is an initiative of Pfizer. This project was supported by an unrestricted grant from Pfizer, reference number 007-04.
