ABSTRACT: In contrast to the equilibrium structure of the homoaromatic C₂ homotropenylium cation, C₂H₂⁺ (1), which supports a pinched diatropic ring current, the C₂v transition state (2) for inversion of the methylene bridge of 1 is antiaromatic and supports a two-lobe paratropic π current, as detected by plotting B3LYP/6-31G** isopolaric elemental current maps. Participation of the bridge CH bonds is crucial for the change in global character of the current in the transition state, as shown by the quenching of its paratropicity on substitution of H by F. Orbital-based arguments allow rationalization of this transition between homoaromaticity and hyper(conjugative) antiaromaticity. More generally, the hyperconjugative ring current in a family of C₂v planar-constrained geometries of (CR₂)C₈N=CHX⁻, homoaaromatic C₂ homoannulenes (R = H, F) can be switched from paratropic (antiaromatic) to diatropic (aromatic) by variation of ring size, charge, and bridge substituent. An orbital-based counting rule accounts for these systematic trends.

INTRODUCTION

Aromaticity appears in many guises, each with an associated signature ring current. In the case of the archetypal 6π-

![Figure 1. Optimized structures of two conformations of the homotropenylium cation C₈H₆⁺: (a) Cₑ equilibrium structure, I (in orthogonal views, identifying bridge exo and endo positions), and (b) C₂v transition state, 2.](image)

Homoaromatic homotropenylium cation (I, C₈H₆⁺)3−7 aromaticity of the system is corroborated by current-density maps, which show a π ring current of a peculiar character.8 At the equilibrium geometry of 1, a double horseshoe of conventional π current pinches down to a single σ current that flows through space under the conjugation-breaking CH₂ bridge. The experimental evidence for the horseshoe π current in 1 is based on the difference in ¹H chemical shifts δexo and δendo for the two types of bridge methylene site.9 Measurement is complicated by experimental difficulties, but the estimated shift of Δδ = δendo − δexo = 5.8 ppm is supported by ab initio calculation (IGLO/6-31G**//HF/6-31G**: Δδ = 5.1 ppm).10 Equivalent conformations of the homotropenylium cation, I, are formally linked by inversion of the methylene bridge, which swaps exo and endo ¹H nuclei (Figure 1), and can be envisaged as proceeding via an 8π C₂v-symmetric transition state (2), over a relatively high barrier of 93 kJ/mol.11 An alternative “circumambulant” process for this transition was briefly raised but then discounted by Berson and Jenkins.12

More recently, in a computational study of benzylic and cyclic delocalized cations, the C₂v transition state, 2, was found to exhibit a positive NICS(0)14 value of +11.0 ppm at the GIAO-SCF/6-31+G*/B3LYP/6-311+G** level of theory, which would generally be taken as indicative of canonical π antiaromatic character. This value mirrors the negative NICS(0) value of −11.1 ppm computed at the same level of theory for the equilibrium structure, Cₑ.13 NICS values can be subject to various competing effects and are not always reliable...
induces a change in the transition-state (IGLO/6-31G*//HF/6-31G*): 1 R(C1···C1) = 2.285 Å, \( \chi/10^{-6} \text{ cm}^{-1} = 86.4 \text{ calcd} \) 72 exp16 and transition-state (IGLO/6-31G**//HF/6-31G*): 2, R(C1···C1) = 2.675 Å, \( \chi/10^{-6} \text{ cm}^{-1} = 52.9^{19} \) structures; in view of our results, this magnetizability difference points to ring-current aromaticity of the transition state.

Thus, we have the interesting situation of reversal of aromaticity along a reaction coordinate, corresponding to interconversion of aromatic systems via an antiaromatic transition state. We explore this process further here. We present direct theoretical evidence for the paratropic (antiaromatic) character of the \( C_{2v} \) transition state and show that this tropicity is critically dependent on the energies of the CH bonds of the CH2 bridge, which have a \( \pi \)-like combination that can interact with the \( \pi \) system of the ring. This energy match would not be found in the CF2 analogues of 1 and 2 (i.e., 3 and 4), and the transition state 4 is accordingly found to be (weakly) diatropic (aromatic). Our calculations will be used to document the reversal of aromaticity between 1 and 2, and to suggest a model for rationalizing the net tropicity of planar-annulenes18−20 although the physical mechanism for these changes (Möbius twisting via cis/trans isomerization) is different from the present case where geometric motion induces a change in effective electron count.

### RESULTS/DISCUSSION

Geometries of 1−4 were optimized at the B3LYP/6-31G** DFT level using Gaussian09.21 In terms of the potential energy surfaces, if the local minimum 1 (\( C_{2v} \) symmetry) is taken as the zero of energy, 2 is a transition state (\( C_{2v} \) symmetry, single imaginary frequency \( 125i \text{ cm}^{-1} \)) with a relative energy of 91 kJ mol\(^{-1}\) (corrected for zero-point vibration, see Supporting Information S1). Minima and transition states were identified by Hessian calculations (see Supporting Information S1 and S2). Subsequently, current-density maps were calculated at the same level of theory using the ipso-centric CTOCD-DZ approach (CTOCDDZ/B3LYP/6-31G**//B3LYP/6-31G**)22 implemented in the GAMESS-UK22 and SYMSO24 packages, as previously8 used for 1. The advantages of this distributed-origin method for calculation of currents, in terms of economy and interpretability, are well documented25,26. A key feature for the present application to 1 and 2 is that the method gives physically nonredundant orbital contributions to current. These can be based on the use of either canonical (delocalized) or localized molecular orbitals (CMOs or LMOs) to partition the total \( \pi \) current density. This proves to be essential in the understanding of the maps and the interpretation of the currents in 1 and 2.

In the low symmetry of system, 1, there is no formal separation of \( \sigma \) and \( \pi \) molecular orbitals, and the CMOs necessarily have mixed character. However, each carbon atom not involved in the methylene bridge has three coplanar single bonds,8 allowing definition of an orthogonal \( \pi \) atomic orbital on each center27 and construction of \( \pi \)-like localized molecular orbitals (LMOs) by combination. Nearest-neighbor interactions are of \( p_x-p_x \) type around the formally conjugated portion of the ring but have \( p_x-p_x \) character in the \( C_1-\cdots-C_7 \) bridge region. Pipek–Mezey localization28 was used to find these combinations and their contributions to current.29 The Pipek–Mezey LMOs for 1 here include three ring-localized \( \pi \)-like occupied orbitals, contributing both the horseshoe of conventional \( \pi \) ring current and the single stream of current crossing from carbon \( C_1 \) to \( C_7 \) under the methylene bridge, as seen in Figure 2. Note that the two CH bonds in the bridge give rise to two LMOs which contribute neither to the \( \pi \) current around the ring nor to the current crossing the \( R(C_1\cdots C_1) \) gap in \( C_1 \).3 However, in the \( C_{2v} \) symmetry of 2, these CH-bonding orbitals make a contribution (see below).

The transition state 2 has higher \( C_{2v} \) symmetry and hence a well-defined \( \sigma/\pi \) separation. Figure 3 shows the calculated \( \pi \) current maps for this system. The gap-jumping diatropic ring current of 1 has disappeared and has been replaced by a paratropic circulation that follows closely the line of carbon centers, with strength 0.096 au (as measured by \( j_{\text{max}} \) in-plane maximum in the current density per unit inducing

---

**Figure 2.** Diatropic ring current in the homotropenylium cation, 1, attributable to the combined contributions of the three occupied \( \pi \)-like localized molecular orbitals obtained from the Pipek–Mezey procedure. (a) The holeshoe current in the ring; current density at 1.75 \( q_0 \) below the \( C_1\cdots C_1\cdots C_1 \) reference plane on the side away from the bridge (\( j_{\text{max}} = 0.092 \text{ au} \)). (b) The gap-crossing current under the bridge: current density in a plane perpendicular to the \( C_1\cdots C_1\cdots C_1 \) reference, \( 1 q_0 \) away from the \( C_1\cdots C_1 \) centers, on the endo (ring) side of the bridge (\( j_{\text{max}} = 0.101 \text{ au} \)). Plotting conventions: arrows show the current density resolved into the plotting plane; contours show the modulus of the full current-density vector; anticlockwise circulations are diatropic and clockwise circulations paratropic. An arrow representing the “standard” benzene ring current, calculated at a plotting height of 1 \( q_0 \), is included for comparison (modulus \( j_{\text{fmax}} = 0.079 \text{ au} \) at the present level of theory22).

**Figure 3.** CMO contributions to current density of \( C_{2v} \) transition state 2, from (a) all four occupied \( \pi \)-orbitals, (b) the paratropic \( \pi \)-HOMO, and (c) the diatropic \( \pi \) complement of the HOMO (i.e., map a minus map b). Maps are plotted at a height of 1 \( q_0 \) above the molecular plane, with plotting conventions and benzene standard arrow as in Figure 2. Orbitals of \( \pi \) character are defined solely by their symmetry with respect to reflection in the plane of the ring.
external magnetic field), stronger by 20% than the standard diatropic π current in benzene.

Following the ipsocentric approach, in which total current density is partitioned into orbital contributions governed by rotational and translational symmetry selection rules,\textsuperscript{29,30} the paratropic current is seen to arise almost entirely from the π−π* HOMO–LUMO-induced virtual excitation and is rotationally allowed as it preserves the number of angular nodes in the active orbitals. There is a close analogy with the characteristic antiaromatic current of the eight-membered cyclooctatetraene (COT) ring in planar geometries.\textsuperscript{30} Exactly as in planar-constrained COT, the main paratropic HOMO contribution to π current in 2 (Figure 3b) is partially canceled by a weaker diatropic circulation arising from translationally allowed node-increasing excitations into the LUMO from orbitals lying immediately below the HOMO (Figure 3c). The HOMO contribution itself is dominated by the HOMO−LUMO excitation, as confirmed by spectral decomposition\textsuperscript{31} (see Supporting Information S3). Seen in this way, 2 offers a textbook example of how the two-electron paratropic current arises in an 8π system.

The total current can be described in a basis of LMOs. This LMO description is less economical but more revealing. The occupied π molecular orbitals of C\textsubscript{2}v have symmetry a\textsubscript{2} + 3 b\textsubscript{1} and correlate with the three occupied π orbitals of a heptatriene moiety plus the π-like combination of the CH bonds of the methylene bridge. As Figure 4 shows, these four orbitals taken together give rise to the closed paratropic ring current, with the heptatriene-like LMOs contributing a horseshoe of π ring current as in 1, with continuity of the twin-loop circulation supplied by the π orbital of the CH\textsubscript{2} bridge.

One minor technical point alluded to earlier concerns the way that current arising from the CH-based π-like orbital is calculated. The localization procedure produces two spatially separated CH bonds (rather than π and π) combinations. Inclusion of both LMOs is therefore necessary for the maps shown in Figure 4; each of these orbitals makes a contribution to one loop of π ring current but their in-phase combination also gives rise to a small diatropic σ current concentrated in the
Figure 7. CMO contributions to current density of the bridge-fluorinated \( C_5 \) transition state, 4, arising from (a) all occupied orbitals of \( \pi \) symmetry, (b) the paratropic \( \pi \)-HOMO, and (c) the diatropic HOMO complement (the difference of maps (a) and (b)). Plotting conventions and benzene reference arrow as in Figure 3.

Figure 8. Classes of aromatic and antiaromatic \( C_{2v} \)-symmetric bridged annulene species \((C_{\nu}R)_{n-1}H_{n-1}\) defined by the electron counting rule \( n_x = N - 1 - q + \delta \), where \( \delta \) pseudo-\( \pi \) electrons are donated by the bridge.

region exo to the bridge. This inevitable CH-based \( \sigma \) contamination accounts for the small differences between the canonical (four-orbital) and localized (five-orbital) \( \pi \) maps shown in Figures 3a and 4a, respectively. However, both are describing what is effectively a pseudo \( [8] \)annulene containing eight \( \pi \)-electrons.

In contrast with homoaromatic 1, the bridge in 2 is active in transmission of the current, leading to hyperaromaticity/antiaromaticity (also known as hyperconjugative aromaticity/antiaromaticity\(^{32} \)). A pictorial model (Figure 5) can account qualitatively for the variation of the main features of the currents along the \( C_3 \)-to-\( C_{2v} \) reaction coordinate 1-to-2: the carbon centers at the “ends” of the bridge in 1 (i.e., \( C_1 \) and \( C_7 \)) have planar \( sp^3 \) bonding with \( p_x-p_y \) overlap across the gap, and the \( \pi \) combination of CH bonds is not sterically available in 1. As the system moves along the inversion coordinate, \( p_x \) functions at the ends of the bridge \textit{dis-rotate} toward parallel alignment with each other, and concomitantly the \( CH_2 \) group descends into the widening gap between carbon centers \( C_1 \) and \( C_7 \). In the limit, the cyclic “\( 6\pi \)” system, completed by a \( \beta_{\sigma\tau} C-H \) resonance integral across the gap, becomes an “\( 8\pi \)” system with two \( \beta_{\sigma\tau} C-H \) integrals crossing the gap.

An IRC-following calculation suggests that the switchover from diatropic to paratropic ring current takes place roughly halfway along the intrinsic reaction coordinate defined by the geometries of 1 and 2 (see Supporting Information S4). The crucial role of the CH bonds in providing continuity in the paratropic ring current of 2 is already evident from this localized analysis and is confirmed by comparison with the analogous system where there are CF bonds in the bridge. This fluorinated system 3 also has \( C_1 \) symmetry at equilibrium \( R(C_{1v} \cdots C_{1v}) = 2.254 \text{ \AA} \) (see Supporting Information S1 and S2)) and supports a homoaromatic ring current with the “pinched” signature found in 1 (Figure 6).\(^{3}\) However, the \( C_{2v} \) symmetric transition state 4 (relative energy corrected for zero-point vibration 70 kJ mol\(^{-1} \), with single imaginary frequency \( 51 \text{i cm}^{-1} \)) for interconversion of minima 3, is strikingly different from 2 in that it now displays a weak diatropic rather than a strong paratropic current. As Figure 7 shows, the total \( \pi \) current in 4 is dominated not by the \( \pi \)-HOMO orbital contribution, which is still weakly paratropic, but by the diatropic contribution from the HOMO-complement.

Comparative analysis of the frontier orbitals for 2 and 4 reveals the source of this discrepancy. The \( \text{HOMO} \rightarrow \text{LUMO} \) gap is larger in 4 (\( \Delta_{\text{HL}}(2) = 2.62 \text{ eV}, \Delta_{\text{HL}}(4) = 3.34 \text{ eV} \)) and there is an accompanying change in local topology of the HOMO; in 2 the \( \text{HOMO} \rightarrow \text{LUMO} \) excitation is rotational in character, as both orbitals have four lobes on each face of the ring, one localized on the \( CH_2 \) fragment, whereas in 4 reduced participation of the \( CF_2 \) fragment leads to a HOMO that has three lobes on each ring face and a poorer rotational match to the LUMO (see Supporting Information S5). Both effects contribute to attenuation of the orbital paratropic current: if the energy difference is too large, continuity of the current will be disrupted; if the nodal character is unchanged, the sense of the current will not reverse. In the \( CF_2 \) analogues of 1 and 2, the \( \pi \) combination of CF bonds has a lower energy, resulting in poorer interaction with the ring \( \pi \) orbitals, even in the optimal alignment of the planar transition state (see Supporting Information S5).

An interesting alternative interpretation of the effect of \( F \rightarrow H \) substitution is proposed by Fernández et al.,\(^{17} \) who suggest...
that the CR$_2$ unit in charge-neutral planar bridged cyclo-polyenes always provides a pseudo-π orbital and adds two to the "π" electron count for R = H, but zero for electronegative R = F. This binary choice concentrates on electron counting rather than the subtle continuous variation of orbital energetics and topology and is based on a very restricted choice of bridge groups.

- **GENERALIZATIONS**

Finally, we note that similar reasoning can be applied to give a Hückel-like model of currents in the planar-ring geometries of analogues of 2 and 4, allowing for different ring sizes, charges, and electron counts (Figure 8). Consider a C$_{2v}$-symmetric structure for the species (CR$_2$)$_{C_{N-1}H_{N-1}}$, derived formally by insertion of a (CR$_2$) bridge in a C–C bond of a (possibly charged) [N-1]annulene. The precise form taken by the model for ring current in this species depends on the role assigned to the bridge. In the version implied by the interpretation of Fernández et al.,$^{17}$ the bridge is assumed always to provide a pseudo-π orbital compatible in energy with the conventional sp$^2$ π system of the remainder of the ring. Differences between CR$_2$ bridges are attributed to differing numbers of electrons donated by the bridge, governed by changes in relative electronegativity of R. The (CR$_2$)-bridged C$_{2v}$ structure is

---

**Figure 9.** Current-density maps for C$_{2v}$-constrained bridged homoannulenes, (CR$_2$)$_{C_{N-1}H_{N-1}}$, with (a) R = H, and (b) R = F. Species are arranged according to N and q as in Figure 8. Maps show total current arising from the full set of canonical π-like orbitals.
then a pseudo-\([N]\)annulene. Counting gives \(n_{\pi} = N - 1 - q + \delta\) electrons in the \(\pi\) system, where \(\delta\) is the number of electrons donated by the \((\text{CR}_2)\) group, and in the cases considered, \(n_{\pi}\) is always an even number. In the case of \(\text{CH}_2\) or \(\text{C}^2\text{SiMe}_3\), the bridge is taken to donate two electrons, but in the case of \(\text{CF}_2\), none.\(^{17}\) Ring currents in the species \((\text{CR}_2)\text{C}_n\text{H}_2\text{C}^2\text{SiMe}_3\) can then be derived from the ipsocentric model for annulenes by consideration of the nodal structures of the HOMO and LUMO.\(^{30}\)

When \(n_{\pi}\) is divisible by 4, the \(\pi\) HOMO and LUMO for the planar geometry are connected by a rotationally allowed transition, giving rise to a paratropic \(\pi\) HOMO current in the ipsocentric model.\(^{30}\) Conversely, when \(n_{\pi}\) is not divisible by 4, the HOMO–LUMO transition is translationally allowed and the \(\pi\) HOMO current is diatropic. Thus, for fixed \(N\) and \(q\), if the \(\text{CH}_2\)-bridged species is paratropic, the \(\text{CF}_2\)-bridged species is diatropic, and vice versa. Current strengths may differ, as excitations span energy gaps of different sizes.

To test this electron counting scheme, calculations were carried out on an extended series of neutral and charged systems \((\text{CR}_2)\text{C}_n\text{H}_2\text{C}^2\text{SiMe}_3\) with \(R = \text{H}\) and \(F\), \(N = 3\) to \(10\), and \(q = -1, 0, +1\), with \(q = 0\) for odd \(N\), and \(q \neq 0\) for even \(N\), making 24 closed-shell systems in all (see Supporting Information S6). Structures with the ring constrained to planarity were optimized at the B3LYP/6-31G** level, and ipsocentric current-density maps were computed at the CTOCD-DZ/B3LYP/6-31G** level.

According to the case, minima, transition states, or stationary points of higher order were found (see Supporting Information S7 and S8 for details). Where the planar geometry corresponded to a transition state, the imaginary frequency represented the expected conjugation-breaking mode in which the bridge moves out of the molecular plane to yield a \(C_2\) symmetric minimum (see Supporting Information S9 for details). Stationary points of higher order were typically found for the larger values of \(N\) (e.g., \(N = 9\) and \(10\)), with extra imaginary frequencies for distortion of the ring. However, we note that ring currents have been shown to be surprisingly robust under such conformational distortions, e.g., in the conversion of planar COT to the equilibrium tub shape,\(^{29}\) where the \(\sigma/\pi\) distinction is lost as soon as the structure departs from planarity, but an identifiable \(\sigma\) current persists for much of the pathway.

The current-density maps are collected in Figure 9. It can be seen that the new \(n_{\pi}\) rule is successful in predicting the sense of \(\pi\) ring current for each planar or planar-constrained system, capturing the aromatic/antiaromatic alternation with changes in either electron count or ring size, and the inversion of behavior between H and F species at the same electron count. This is effectively a generalized Hückel counting rule.

The NICS calculations of Fernández et al.\(^{17}\) on the neutral odd cyclic polyenes are consistent with the currents calculated here, fitting neatly into the overall pattern for neutral and charged systems with different ring sizes.

In the pure “annulene” form described above, the model is an oversimplification, as it ignores differences in energy between \(\text{C}–\text{C} \pi\) bonds and the \(\text{C}–\text{R} \sigma\) bonds of the bridge. If the discrepancy in energy is too great, loss of conjugation and extinction of ring current can be expected. If desired, this feature could be accommodated by treating the \(\text{CR}_2\) bridge as a pseudo heteroatom with full electron count of two, but with variable Hückel parameters. The general tendency would be for gaps to open up and for current to decrease, as the parameters were allowed to diverge from the values appropriate to \(sp^2\) carbon. As the maps in Figure 9 show, current is generally weakened when F is substituted for H in the bridge, which is consistent with a modification of the pure annulene model. The advantage of a variable-parameter model would be that it could accommodate “mixed” situations. If the bridging group were CHF, for example, the parameters would be close to averages of \(\text{CH}_2\) and \(\text{CF}_2\) values, and indeed, when ab initio current maps are calculated for this mixed system, the \(\pi\) current is found to be very weak and paratropic (see Supporting Information S10). It is not clear how a pure electron-counting model would deal with this case.

**CONCLUSION**

Mapping of currents has been used to explain some initially surprising reversals of ring current in homoannulenes, giving a more detailed picture that could not be deduced from single-point calculations of properties such as NICS values, or solely by drawing MO pictures. NICS values have multiple contributions,\(^{15}\) and although electron delocalization is a precondition for global current, the fact that delocalized orbitals can be constructed does not inevitably lead to ring current.\(^{33}\) The interplay of orbital nodal character and energetics, however, can be used to derive a simple orbital-based interpretation of aromaticity and antiaromaticity within the homoannulene family.
